The cases to be presented below are divided into 3 groups for analysis. In the first group ovarian tissue had been previously removed in most instances because of pain in the lower abdomen. Pain recurred following operation and when the patients came under observation of the author its source could be identified as the ovary. In the second group the patients were observed before any surgery was performed. In all of them careful observation revealed the ovary to be the source of the pain and in none was it of sufficient cyclic regularity to be classed as *Mittelschmerz*. Cases of cyclic intermenstrual pain or *Mittelschmerz* comprise the third group.

The frequency with which signs of ovarian insufficiency were associated with ovarian pain suggested that the latter is part of a syndrome of ovarian insufficiency. When looked for pain and excessive tenderness of the ovary were found frequently enough to be considered criteria of this condition. The beneficial effect of estrogen in the treatment of many of these cases strengthened this impression and the relief of *Mittelschmerz* without suppressing ovulation illustrated by the cases in group 3.

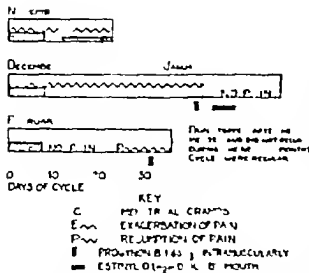

Chart K.M. 30 year old woman. Large irregularities before menstrual cycle, small irregularities after removal of ovarian tissue.

supports the theory that the human ovary, like that of the rabbit, requires the estrogen produced by the growing follicles for completion of the cycle of follicular growth, ovulation and corpus luteum formation and survival and the quantity of estrogen and hence the amount or mass of ovarian tissue is of the greatest importance.

Group 1. Ovarian insufficiency and pain following loss of ovarian tissue. There are 15 patients in this group, none of whom was permanently benefited by the removal of ovarian tissue. Pain recurred in all and 13 of them experienced other symptoms of ovarian failure after operation. Pain was relieved by estrogen in most of the cases in which it was tried, 10 out of 11. One case considered the most typical is described in detail.

K.M. This 30 year old woman began to have recurrent pain in the right lower quadrant of the abdomen at the age of 12, about a year after the menarche. It was frequently associated with nausea and vomiting and 3 years later an appendectomy was done because of it. Attacks of pain continued. She was first seen in the Out Patient Department at the age of 15, about 8 months after the operation. Menstruation 4 days were at 28 day intervals. Findings were normal except for abdominal tenderness in the right lower quadrant. The introitus was normal and the hymen was intact. At this time the pain was irregular, described as sharp and shooting, occurring several times a week and lasting as long as a day. During the next 8 years intermittent pain con-

tinued but was less troublesome. She married and at the age of 22 had a normal pregnancy with a normal infant. Seen again about a year after birth of the child, she again complained of pain in the right lower quadrant, now beginning 2 days after the cessation of the menses. Menstrues were at 24 to 28 day intervals lasting 4 to 5 days without dysmenorrhea. Examination revealed ovaries of normal size, the right one usually tender. Three months later the left ovary was more tender and 3 months after that the right ovary was again described as the more sensitive.

At no time was there any evidence of infection. She was not seen again in this clinic until 5 years later. She now complained of pain on the left side and reported that 3 years before, 2 years after her husband's death, her right ovary had been removed at another hospital because of the pain previously complained of. After the operation she began to have irregular bleeding and she experienced hot flashes. She began to have menstrual cramps for the first time. About 6 months after the ovariectomy the pain in the other ovary began. Inquiry revealed that exacerbations of the pain in the left lower quadrant occurred in about mid-cycle along with bleeding. This pain was present most of the time, however, and in the acute phase it radiated down the left thigh across the pelvis into the upper left leg and the lumbar area on the left. Examination was negative except for the extreme tenderness of the left ovary estimated to be 3 centimeters in diameter. The anamnesis during 4 months in this case is shown graphically in Chart 1.

Examination of the right ovary removed 3 years before revealed normal ovaries to size.

Reactions like those illustrated in this group of cases have been observed by Karmakar. He mentions 89 cases in which irregular menstruation, bleeding and pain in the left ovary followed removal of the right ovary at the time of appendectomy.

Group 2. Irregular ovarian pain. The 15 patients in this group all experienced pain in one or both lower quadrants of the abdomen for periods ranging from 2 weeks to 10 years. Increased tenderness of the ovary or in the region of the ovary on the affected side was demonstrated in all. In none was there any evidence of abnormal ovarian enlargement or adnexal disease. Both ovaries were palpable in 36 cases. In 19 only one could be felt and in 20 neither one could be outlined. In 9 cases it was possible to check the findings at laparotomy.

The onset of pain occurred as early as the ninth and as late as the thirty-eighth year. The largest number of patients, 35, first ex-

perienced pain in the third decade. Twenty six first noticed pain between the ages of 10 and 20. Onset occurred in the fourth decade in 13 cases. One woman of 21 began having recurrent pain before puberty at the age of 9 years. In 9 cases the pain was cyclic at first and later became irregular. One of these, operated upon in an early attack of pain in the right lower quadrant was found to have intraperitoneal hemorrhage from a ruptured graafian follicle. This was the only patient of those subjected to laparotomy in whom this condition was found. Suture was not necessary, and the ovary was left alone. Irregular pain began during the following year.

Signs or symptoms of ovarian insufficiency were present in 59 cases. Hot flashes occurred in 27 cases, intercytic bleeding in 19, abnormally irregular cycles (2 weeks to 2 or 3 months) in 16, menorrhagia in 12, hypomenorrhea in 9, and amenorrhea in 3. Thirty six patients had one of these symptoms: 19 had 2 and 4 had 3. Sixteen patients had none. The pain was classed as slight in 7 cases and as moderate to severe in 68. In 9 of the latter group with severe pain laparotomy was done. There were other signs of insufficiency in all of these: 6 had 1, 2 had 2, and 1 had 3. Three of the 7 patients with slight pain had amenorrhea, 1 had irregular cycles.

Pain occurred most frequently on the right side. In 46 of these 75 cases it was exclusively on the right. In 7 it was experienced only on the left. Either side (one side for a time and then the other) or both sides were involved in 22 cases. Of these the right was the more troublesome in 19, the left in 3.

Fifty-eight patients had menstrual cramps of varying severity. In 21 cases the ovarian pain was aggravated at the time of the menses. In 50 cases it was not, and in these the pain was likely to be less troublesome during menstruation.

Thirty six patients experienced radiation of the pain into the thigh on the affected side. More may have had this symptom for the information was not always volunteered when the pain was not severe, and in the early cases patients were not questioned concerning it. The pain was not well localized. Except in severe cases where it radiated to the foot, it usually did

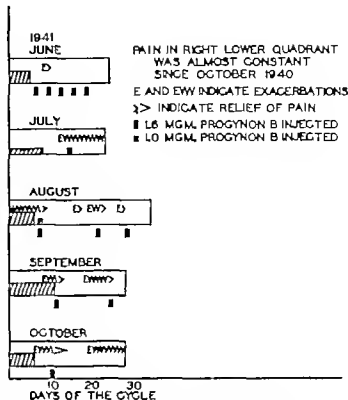

Chart 2. M.M. Large rectangles indicate the menstrual cycle; small shaded rectangles, the menstrual flow.

not extend beyond the knee. It is of interest that radiation into the thigh of pain of ovarian origin was noted 70 years ago (6). In 10 patients pain seemed to radiate to the back in the sacroiliac region of the affected side.

Two cases of irregular pain are reviewed in detail. The first is one of acute onset of pain in a young woman. The pelvic organs were examined at laparotomy and a biopsy of the painful ovary was obtained, but long term follow up was not possible.

D.S. This 30 year old woman complained of intermittent, and at times incapacitating pain in the right lower quadrant of the abdomen for the past 10 days. Her last menstrual period occurred 2 days after the pain began and lasted one day. The pain became worse after the one day flow, and at the time she was first seen it was almost constant. Her appendix had been removed.

Menarche at 12, her periods had been of 3 days duration at 18 day intervals until 3 months before when they became shorter, only 1 day, and were accompanied by more pain, consisting of lower abdominal cramps. General examination was negative except for tenderness in the right lower quadrant. Pelvic examination revealed a very tender mass the size of a normal ovary on the right side. Rabbit ovulation test for pregnancy was negative.

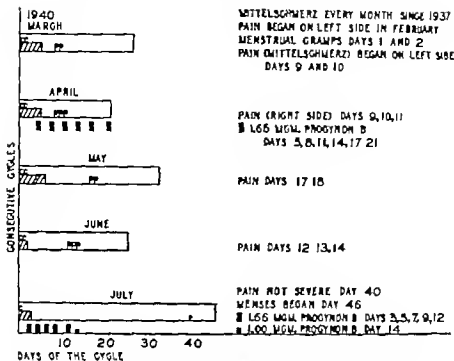

Chart 3. Case of F.S.

Because of the negative findings, the patient was observed. The pain, however, became more severe, and on examination a days later the mass on the right, thought to be ovary was more tender so much so that operation was decided upon.

At operation the pelvic organs were found to be normal in appearance. The right ovary larger than the left, and apparently the mass which had been felt on examination, was not over 5 centimeters in its greatest diameter. It appeared tense however and on incision several follicles were found in the central portion. The largest of these were carefully resected and the incision was closed with fine catgut. No corpora lutea were identified in either ovary.

Histological examination of the tissue removed showed normal ovarian tissue including cellular stroma, the walls of several graafian follicles, and part of a corpus albicans.

There was no recurrence of pain during the 3 weeks following operation.

This case is the type in which one ovary the apparent source of incapacitating pain, is likely to be removed.

In the following case operation was avoided in an early acute attack of pain. The subsequent course over a period of 2½ years is summarized.

M. M. This unmarried woman was first seen in 1941 at the age of 22. She had experienced recurrent attacks of pain in the right lower quadrant of the abdomen for 3 months. The first attack occurred

midway between two menstrual periods and was accompanied by scant bleeding of 3 days' duration. The next attack, a month later was unaccompanied by bleeding. It was of such severity associated with nausea, that appendicitis was suspected. Vital signs were normal however and the classical signs of appendicitis were lacking. Since then, attacks had become more frequent, and she had almost constant soreness in the right lower quadrant, aggravated by walking. For the past 3 days, there had been scant vaginal bleeding which had begun 2 to 3 weeks after the last menstrual period. She complained also of some pain in the right sacroiliac region.

The menarche had occurred at the age of 14, and periods had been irregular, 14 to 35 days, lasting 8 to 10 days. She always experienced crampy pelvic pain during the flow preceded for a few days by aching in the right lower quadrant like the pain of which she complained. The flow was often extensive and she frequently remained in bed during the first day. General physical examination was negative. On pelvic examination, the right ovary was found to be markedly tender although within normal limits of size. Basal metabolic rate was -13 per cent. The patient was observed during the next 3 years, during which pain was intermittent and menstrual irregularity persisted. Treatment consisted principally of small doses of thyroid over long periods and injection of estrogen 1 or 1.6 milligrams of progyron B at various times during the cycle. Injections were almost always followed by relief of the pain, at times for as long as a week, but usually for a day or two. On more than one occasion, when the estrogen was given frequently in the early part of the cycle, men-

Chart 4. Case of F.S.

strual cramps were abolished indication that ovulation had been suppressed

Typical responses of the ovarian pain to estrogen are shown in the diagram of 5 consecutive cycles in Chart 3. The pain began as rather typical *Mittelschmerz* but after 2 months it became practically constant. Exacerbations frequently occurred in mid cycle however when ovarian activity would be expected to be at a peak. This patient married in 1946. A year later she had a normal pregnancy resulting in a full term child. Pain continued irregularly through the early months of pregnancy but ceased after about the fifth month.

Administration of estrogen was followed by relief of pain in 3 out of every 4 cases in this group. It was tried in 53. No effect was observed in 14. In 39 there was relief and 23 of these were classed as remissions since symptoms were definitely improved for more than a week. The reaction to estrogen could usually be determined by injection of 10 to 16 milligrams of estradiol benzoate (see Chart 2). In 2 cases pain became cyclic following treatment with estrogen.

Anyone who has tried to evaluate the effect of a therapeutic agent administered for the relief of subjective symptoms realizes the difficulty of convincing himself that any improvement is not the result of suggestion. The menstrual aberrations however improved

along with the pain, and injection of other substances was without similar effect. The degree of relief appeared to vary with the dosage. The benefit from 16 milligrams of progynon B was often obviously greater than from 33 milligram. Pain was increased by chorionic gonadotropin and that of pregnant mare's serum.

In the most severe cases where the pain was constant and incapacitating just as in an attack of *Mittelschmerz*, estrogen was ineffective. Indeed when most needed it did not help. These cases present a very difficult problem. Ovarian specimens were taken for biopsy and the albuginea was cut in 2 cases with only temporary relief. Four cases in group 2 were treated with bilateral section of the ovarian plexus and vessels as described by Bigelow. There was temporary relief in 3, but the longest remission was only a month. In one case the pain became cyclic and it has remained so for more than a year. Two of the patients who experienced temporary relief from section of the ovarian plexus were further treated with presacral and bilateral lumbar sympathectomy (removal of the first to the fourth sympathetic ganglia on both sides). Both patients developed pain again after several

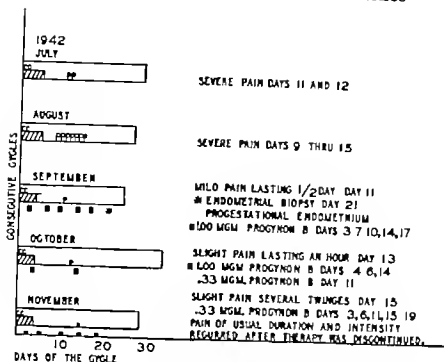

Chart 5. Case of P.S.

months of relief. In one it was on the opposite side. The pain has been less severe in both patients, however, and one has become pregnant.

The similarity of the symptoms and signs of this condition to those of chronic inflammatory disease is great. In some patients with long hospital records the diagnosis of salpingitis had been made but it was found to be unproved at the time and subsequent findings made it untenable. In most of the patients with repeated hospital admissions diagnosis of abdominal pain cause undetermined, had been made. Endometriosis also has features in common with this condition, and it was considered particularly in those patients in whom the pain was aggravated by the menses. Unlike endometriosis pelvic findings are normal in these cases even after many years of symptoms. There does not appear to be any unusual infertility.

It will be noted that pain in the right ovary is much more frequent than in the left. This suggests that the right ovary is the more active. This may be true. That the two ovaries are not equally functional has been noted (2). In 64 cases of cesarean section in which he could find it Williams noted the corpus luteum in the right ovary 36 times and in the left

28 (29). Presumptive evidence of the side on which ovulation occurred may be gained from the location of tubal and ovarian pregnancy. Ward Ekas found in a review of the cases of ectopic pregnancy at the Strong Memorial Hospital that in 180 cases it occurred 104 times on the right side and 76 on the left. According to Hartman ovulation occurs more frequently on the right side in the monkey.

Group 3. Cyclic intermenstrual pain or Mittelschmerz. The similarity of the pain so far described with *Mittelschmerz* is apparent. In 5 of the 15 cases in group 1 the pain which followed removal of one ovary was cyclic, and it is of interest that in the first case described by Wharton and Henriksen in their paper on periodic intermenstrual pain, typical *Mittelschmerz* made its appearance after the removal of one ovary.

Eleven of 25 unselected cases of *Mittelschmerz* had signs of ovarian dysfunction. There was intercytic bleeding in 8, menorrhagia in 2 and hot flashes in 2. The occurrence of intercytic bleeding with *Mittelschmerz* has been noted (22). In 8 cases treatment with estrogen was followed by relief of pain. Ovulation at times was prevented by large doses. In fact the original intention was

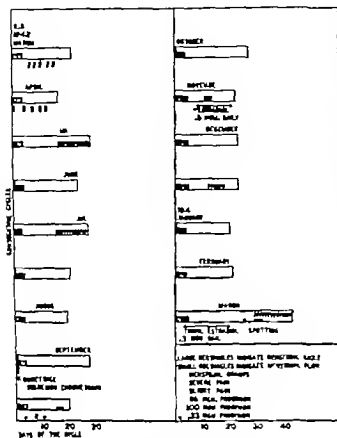

Chart 6 Case of R.B.

to give the patient relief from severe and prolonged pain by prevention of ovulation. But with smaller amounts pain in some cycles was reduced to insignificance, suggesting that ovulation was not prevented and in other cycles where there was no pain at all endometrial biopsy indicated that ovulation had occurred. Two cases treated with estrogen are described.

FS This woman tripara, began to have *Mittelschmers* in 1937 when she was 32 years old. The pain occurred on either side 9 to 17 days after the onset of the menstrual period and usually lasted 3 or 3 days. *Mittelschmers* began 3 years after the birth of her last child. Pelvic findings were normal.

Periods of observation and treatment in 1940-1941 and 1942 are illustrated in Charts 3 to 5. The importance of the amount of hormone given and the timing of the administration is shown. In April 1940 doses of estrogen progynon B sufficient to suppress or postpone ovulation were begun too late in the cycle to have any effect. A slightly smaller amount of the same hormone begun earlier and given more frequently the following July resulted in lengthening the menstrual interval to 45 days, indicating suppression or postponement of ovulation.

In January 1941 she was confined to bed with the most severe pain of her experience. The next month

there was no pain probably indicating an anovulatory cycle rare for this individual. Pain recurred the next month. In May stillbesterol by mouth 1 milligram daily was begun after the *Mittelschmers* and continued through the 16th day of the next cycle. Typical pain occurred 10 days later on the 24th and 25th, 16 days before the onset of the following menses. The following month pain occurred on the 19th and 20th days, again 16 days before the onset of the next menses. Previously recorded *Mittelschmers* had not been later than the 17th day. Ovulation seemed to have been postponed in June by the administration of estrogen.

In August, 1942 the patient again sought relief of her *Mittelschmers* attempts at which had been futile until now because of the unusual persistence that month of the pain which lasted an entire week. Progynon B was again tried in a slightly smaller amount than previously injections of 10 milligram rather than 165 milligrams begun on the third day of the cycle in September and repeated on the 7th and 10th days. Only slight pain lasting about an hour occurred on the 11th day. Since it was not certain that the pain represented *Mittelschmers* estrogen was given again on the 14th and 17th days. That the pain was *Mittelschmers*, modified by the therapy was indicated by the occurrence of menstruation 14 days later and more important by the presence of a normal progestational endometrium revealed by endo-

Fig. 1. Normal balance. The proper proportion of estrogen and gonadotrophic hormone is necessary for ovulation. By its effect on the hypophysis estrogen is keeping the production of gonadotrophic hormone in check. The uterus removes from the circulation an amount of estrogen determined by its size.

Fig. 2. Loss of one ovary. Because of the decrease of

estrogen, there is increased production of gonadotrophic hormone.

Fig. 3. Remaining ovary enlarges, restoring the balance. In response to the increased gonadotrophic stimulus, more follicles become active. If there is enough ovaries time remaining, the estrogen output increases sufficiently to restore the balance and normal function ensues.

metrial biopsy on the 21st day. Similar results were obtained during the next 2 months by the administration of relatively small doses of estrogen. In December 1942 when no therapy was given pain of the usual intensity promptly recurred and it continued regularly at least until 1945. There were however no attacks as prolonged as that in 1942.

R.B. In January 1941 at the age of 26 this nulliparous, married woman began to have crampy midpelvic pain tending to the right side, occurring in the middle of the interval and usually lasting until the menstrual flow began. Meneses had been fairly regular around 4 weeks since the onset at the age of 22 and lasted 5 days. She often had menstrual cramps the first day of the flow.

Pelvic examination revealed two small fibroids estimated at 2 centimeters in diameter. Otherwise examination was negative.

In March, 1942 estrogen therapy was begun as indicated in Chart 6. The original intention was to prevent ovulation, and this seems to have been accomplished at first, March-April 1942 when 1.66 milligram doses of progynon B were given. Later smaller doses were given with equally good results, and it became apparent that the beneficial effect was not dependent on the suppression of ovulation when endometrial biopsy on the first day of the flow following a painless interval, August, revealed secretory endometrium. The occurrence of menstrual cramps after the relief of the *Mittelschmerz* is also significant for although cramps on the first day of the flow are not a constant occurrence they would not be expected to occur in the absence of ovulation (21).

It will be noted that where injections were begun before the 5th day pain was obliterated or relieved, and this was accomplished with as little as .33 milli-

All of the diagrams represent the same phase of the cycle that of follicular growth preceding ovulation. Only one gonadotrophic factor the follicle stimulating, is considered.

gram of progynon B twice weekly (October). The postponement of ovulation by too large a dose of estrogen is illustrated by the last cycle on the chart, February-March, 1943. Ethinyl estradiol (Estroval) 3 milligram daily from the 4th through the 20th was followed 9 days later by the pain accompanied by estrogen withdrawal bleeding, and the cycle lasted 43 days.

A third case H.R. is illustrated in Chart 7. Here there was no *Mittelschmerz* following treatment with estrogen and ovulation was proved by the occurrence of pregnancy. The relief of dysmenorrhea and the sudden change in the fertility of this patient also indicate improved ovarian function.

ETIOLOGY OF OVARIAN PAIN

It would be specious to represent the two types of pain, cyclic and irregular as essentially different. They are probably different manifestations of the same process. That other signs of ovarian dysfunction are seen more frequently with irregular pain than with *Mittelschmerz* suggests that the former is a manifestation of a more serious dyscrasia. The occurrence of *Mittelschmerz* early in the history of some of the cases of irregular pain and its appearance after therapy in others, as well as the exacerbations of pain in midcycle, indicate a close relationship between the two types.

The nature of the underlying disorder is obscure. Ovarian tissue removed from the

Fig. 4. Extreme partial castration. With the loss of much more than half of the original ovarian tissue, that remaining is inadequate and cannot produce the needed estrogen. The imbalance persists, and because of insufficient estrogen there is failure of ovulation. Persistent follicles and cystic changes result.

Fig. 5. With tumors of the uterus, the use of estrogen may increase to the point where an effect similar to that

resulting from loss of too much ovarian tissue is produced. The ovaries enlarge to capacity and then fall because of insufficient estrogen.

Fig. 6. Hysterectomy spares estrogen. It may relieve the condition which is illustrated in Figure 5 for a temporary period of time, but function ceases after a while because the uterus keeps the cycle going by its periodic use of estrogen.

cases in group 1, and the biopsies from 3 cases in group 2 revealed little which at present can elucidate the problem. In 2 of the biopsies a superficial overgrowth of fibrous tissue was noted possibly supporting the idea readily arrived at intuitively that pain is caused by too resistant ovarian fibrous tissue (tunica albuginea). If the albuginea were too dense there would be abnormal pressure as follicles increased in size and if the follicular growth were thus impeded production of ovarian hormones would be reduced. Both the pain and the dysfunction might be explained in this way. The condition described by Goodall as chronic cystic ovarian sclerosis may in varying degrees account for this syndrome. Estrogen may produce its beneficial effect by improving the blood supply of the ovary.

THEORETICAL CONSIDERATIONS

The occurrence of pain in the remaining ovary after the removal of one ovary along with the appearance or aggravation of other signs of ovarian insufficiency the beneficial effect of estrogen and the ovarian failure resulting from extreme partial castration exemplified by case H C have inspired the hypotheses illustrated in Figures 1 through 7.

The uterus should be considered in any theory of ovarian function for its removal is followed first by an apparent increase and

later by an early decline of ovarian activity. The increase is indicated by the prolongation of the life of the corpus luteum by hysterectomy (12). This is explained by the estrogen sparing effect of that operation. The supply of estrogen is greater following excision of the uterus which when present removes estrogen from the circulation (8). Hysterectomy not only spares estrogen however, but it results in the early cessation of the ovarian cycle (16, 17, 18, 4). It seems that in order to function the ovary must be stimulated intermittently. Decline of ovarian activity earlier than normal after hysterectomy may be explained if one assumes that the use of estrogen by the uterus is cyclic, and that wide fluctuations of estrogen and gonadotrophic hormones observed in normal women (23) are necessary for normal ovarian function. Removal of the uterus results in decreased fluctuations in the level of estrogen and is therefore followed by earlier ovarian failure. By the periodic growth of the endometrium the level of circulating estrogen is made to fluctuate. The periodic changes in estrogen concentration cause fluctuations in the hypophyseal gonadotrophic hormone which in turn stimulates the ovary intermittently. Thus the uterus takes an active part in the functional balance of ovary and pituitary. One may think of the uterus as the balancer on a seesaw having the

Fig. 7. Normal function may be thought of as maximum activity of a seesaw. If any of the members gets out of balance inadequate activity results and normal function ceases. Large periodic fluctuations in the amounts of estrogen and gonadotrophic hormone are necessary for normal function, and the uterus enhances the fluctuations by its periodic use of estrogen.

ovary on one end and the pituitary on the other. When the uterus is absent motion of the seesaw representing function becomes feeble and then stops, just as it does if either of the riders on the seesaw stops working (Fig. 7).

Normal function may be thought of as violent or maximum action of the seesaw; various degrees of abnormal function as grades of inadequate activity. Observed relief of functional gynecological disorders with practically any procedure and therapeutic agent can be rationalized if one thinks of them as improving the action of the seesaw. Measures which have been reported to be beneficial include curettage, x-ray to ovaries and hypophysis, injections of gonadotrophics and male as well as female hormones. Anything which sufficiently stimulates or suppresses the hypophysis or the ovary directly or through the nervous system or has an effect on the estrogen utilizing capacity of the uterus may improve the action of the seesaw. Large amounts of estrogen may stop feeble activity altogether by suppression of the hypophysis and make possible a rebound of maximum activity after release of the inhibition. The beneficial effect of 5 milligrams of stilbesterol daily for 20 days in ovarian dysfunction observed by Karnaky and Patton may be explained in this way. The relief of the sterility as well as the *Mistelschmerz* and dysmenorrhea of H. R. in group 3 may thus have resulted from the improved ovarian function produced by a large amount of estrogen.

According to this theory an amount of estrogen sufficient to affect the hypophysis but not enough to suppress it altogether might be expected to dampen the ovarian cycle and result in abnormality. It would neither stop the pituitary-ovarian seesaw allowing for a later rebound, nor would it boost its activity. Ovarian dysfunction would result. This is illustrated by a case described by D'Amour and Woods in which dysfunctional bleeding occurred in a normal woman following daily administration for 2 months of 0.4 milligram of estradiol by injection.

The experiments of Westman, mentioned earlier, indicate that estrogen is necessary apart from any effect on the pituitary for normal ovarian function. It is perhaps pertinent that synergism of estrogen with gonadotrophins in effects of the latter on the ovaries of hypophysectomized rats has been observed (30, 15, 19). Both gonadotropin and estrogen are needed for ovulation and the formation and survival of the corpus luteum. Figures 1 through 4 illustrate a theoretical synthesis of this with the work of Lipschultz showing that on the removal of ovarian tissue relatively more follicles in the remaining tissue are stimulated to activity and function remains normal up to a certain point, but after too much has been removed function ceases and the ovarian remnant becomes cystic. The mechanism of the ovarian failure of extreme partial castration illustrated in Figure 4 may be the same as that associated with lesions of

the uterus which result in increased removal of estrogen from the circulation (Fig. 5 through 7). The association of menstrual irregularities and cystic ovarian changes with uterine fibroids has long been recognized. It has been suggested that the cysts may be the cause of the tumors by the production of excess estrogen (31,32), but it is possible that the uterine tumors disturb the ovarian function by lowering the estrogen to a point where an effect is produced comparable to that caused by the loss of too much ovarian tissue (see Figs. 4 and 5). In the case of growing tumors of the uterus one would expect a gradual increase in the activity of the ovaries until the limit of their ability to produce more estrogen is reached following which the signs of failure would begin. The nature of the tumors some containing more muscle tissue than others and their location some encroaching on and causing an increase in the amount of endometrium would determine their thirst for estrogen and explain the variation in the effects of these tumors in different individuals.

A case which is described by Wharton and Henriksen in their paper discussing periodic intermenstrual pain supports this hypothesis. Intermenstrual pain without ovulation, a sign of ovarian failure, ceased after removal of a myomatous uterus. Description of the case is quoted.

A Jewess aged 30 began to menstruate at the age of 13, the menses had always been regular every 28 days lasting from 6 to 7 days with profuse flow. She had conceived normally in 1930. Intermenstrual pain accompanied by spotting began in 1933. She was operated on at the Sinal Hospital in July 1935, because of uterine myomas with profuse menstrual hemorrhage. We performed the hysterectomy deliberately on the second day of the intermenstrual pain and spotting 9 days after the close of the last menses, expecting to find signs of ovulation. The ovaries however showed no evidence whatever of graafian follicles or corpora lutea. In short, there was no sign of ovulation, although the menstrual cycle had been normal and the patient had the menses that accompany ovulation. Since July 1935 she has been completely relieved of the intermenstrual pain and spotting. The pathologic diagnosis in this case was uterine myomas, endometrial hyperplasia with polyp, and endometrial glands invading the uterine wall.

In one case in group 2 the uterus was removed because of prolonged bleeding which

did not respond to conservative measures. The pain ceased after hysterectomy although the ovaries remained untouched.

The above considerations have dealt with ovarian insufficiency. Hyperfunction of the ovaries is also possible. The syndrome described by Stein characterized by hirsutism and amenorrhea may be caused by hyperfunction of the ovaries for it is relieved by the removal of ovarian tissue. The wedge operation by which it is successfully treated can have little permanent effect beyond the reduction of the ovarian mass.

SUMMARY AND CONCLUSIONS

Ovarian pain can occur in the absence of any demonstrable lesion of the ovary and it may have no regular relation to the menstrual cycle. Its frequent association with menstrual irregularities indicates that the pain is itself a sign of ovarian dysfunction.

This syndrome of ovarian pain, menstrual aberrations and other signs of ovarian failure such as hot flashes occurs in all ages of reproductive life.

The more frequent occurrence of pain on the right side in these cases in addition to other evidence suggests that the right ovary in women is the more active.

By the presentation of cases in which ovarian tissue has been removed in women and the citing of the known effects of partial castration in animals the importance of an adequate mass of ovarian tissue for normal function is shown and the need for conserving ovarian tissue in women is stressed. If one ovary is removed because of this type of pain signs of ovarian insufficiency and pain in the remaining ovary may be expected.

The beneficial effect of therapy with estrogen including alleviation of cyclic intermenstrual pain without the prevention of ovulation suggests that the importance of the mass of ovarian tissue lies in its production of estrogen.

A theory of ovarian function is presented which includes the rôle of the uterus.

ENDOMETRIOSIS AS A CAUSE OF INTESTINAL OBSTRUCTION

PAUL McGUFF M.D. MALCOLM B. DOCKERTY M.D. JOHN M. WAUGH, M.D. F.A.C.S.,
and LAWRENCE M. RANDALL, M.D. Rochester, Minnesota

ALTHOUGH endometriosis¹ with involvement of the small and large intestine is encountered only occasionally it occurs with sufficient frequency to justify giving it a position among the important benign lesions of the bowel. It further commands our interest because it represents a benign condition which at times exhibits such infiltrative tendencies as to make its lesions rather easily confused with malignant neoplastic processes. Especially is this true in those occasional circumstances in which extensive invasion of the intestinal wall by the lesions of endometriosis so compresses the lumen of the invaded segment that complete or incomplete intestinal obstruction ensues. The present report deals with a number of such cases seen and studied from the surgical files of the Mayo Clinic. We feel that throughout the literature the importance of this complication has not been sufficiently stressed.

HISTORICAL REVIEW OF CASES

In 1909 Meyer gave a detailed report of a 45 year old woman who required operative intervention for the relief of a lesion which we should now term obstructing endometriosis of the bowel. In 1918 Lockyer referred to this case in his textbook *Fibroids and Allied Tumors*. In 1920 Cullen reported a case of sigmoidal obstruction on the same basis, which has since become more or less classic among writers of modern textbooks of gynecology.

Sampson in 1921 in his definitive paper on endometriosis described a sigmoidal endo-

metrioma and cleared the field for subsequent recognition of these lesions as local proliferations of ectopic endometrial tissue. In 1923 Judd and Foulds recorded 5 instances of sigmoidal endometrioma, in 3 of which definite degrees of intestinal obstruction were manifest. In 2 of the 3 cases recorded in 1927 by Graves the rectal lumen was compromised. In his third case there was chronic intermittent obstruction of the sigmoid resulting from an infiltrative endometrioma.

A rectal carcinoma was coexistent with a low sigmoidal endometrioma in the case recorded in 1932 by Brane. Endometriosis of the sigmoid portion of the colon produced local obstruction in the case reported in 1935 by Bartlett. In Marmol's case in 1935 a 24 year old woman exhibited signs and symptoms of rectal obstruction resulting from the continual growth of an endometrioma of the rectovaginal septum.

In 1937 Cattell made an important contribution in his report of 17 cases demonstrating involvement of the lower portion of the bowel. Two of 4 patients with sigmoidal endometriosis had almost complete intestinal obstruction. Eight patients exhibited lesions fairly high in the rectum including its junction with the sigmoid and all had experienced some degree of "clinical" obstruction. Definite obstruction was manifest in 2 of the remaining 5 instances in which the rectovaginal septum was the seat of involvement.

In 1940 Glenn and Thornton published their observations on 2 patients who had obstructing endometriomas of the ileum. In a review of the literature they were able to find only 4 additional cases in which there was any degree of obstruction on a similar basis.

Two recent cases of intestinal obstruction caused by endometriosis reported by Thierstein and Allen along with individual reports of a similar nature by Mouat, Lee, Starr

¹From the Division of Surgery, Mayo Foundation and the Division of Surgical Pathology, Division of Surgery and Section on Obstetrics and Gynecology, Mayo Clinic.

²Abridgment of part of a thesis submitted by Dr. McGuff to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery.

³Correct usage dictates that the term "endometriosis" be used to indicate the condition which exists when endometrial tissue is found in any extruterine location. When the lesions are tumefactive the designation "endometrioma" is often employed.

Schuler Gale, Goodwin Behrendt and Neumeyer Okinczyk, Friedman Hepburn, Papin, Josefsson Grigsby Patton and Patton Milnor Blaikley Morrin, Lukins and Lukins, Ben-Asher and Wood Deibert, and Kain comprise the literature on this interesting condition (13 18 20 27 29) the frequency and the importance of which have not received a merited degree of attention in medical writings of the past 25 years.

MATERIALS AND METHODS

Over the period from 1920 to 1946 inclusive, the surgical files of the Mayo Clinic were found to contain records of 48 cases in which the diagnosis of endometriosis of the bowel had been made by a pathologist. In 16 of these 48 cases pathologic material had been removed in an effort to alleviate clinical symptoms and signs of intestinal obstruction caused by cicatrizing endometriosis. The present study concerns these 16 cases.

Material preserved from all of these lesions was secured and studied in gross detail with special reference to such features as the degree of local narrowing of the intestinal lumen the presence or absence of mucosal ulceration the degree of spread above and below the point of major impingement as measured by gross in duration of tissues, the thickness of the intestinal wall and the amount of reactive fibrosis. In those instances in which wide resection had been performed an estimate was made of the degree and duration of the obstruction by comparing luminal diameters of the bowel above and below the level of the lesion and correlating these with the thickness of the uninvolved proximal and distal segments relative to the muscularis propria. Numerous small representative blocks were cut from different levels and these were placed in bottles containing a fresh 10 per cent neutral solution of commercial formalin. Microscopic sections were then prepared using the paraffin method. Routine hematoxylin and eosin stains were employed in this study but in addition the van Gieson method was used for demonstration of fibrous tissue and a stain using the Prussian blue reaction was utilized in order to bring out the presence of hemosiderin.

CLINICAL ANALYSIS

The average age of the 16 patients who had intestinal obstruction caused by endometriosis was 39.5 years with extremes of 31 and 54 years. Seven patients were in the fourth, 8 in the fifth and 1 in the sixth decade of life. There were no colored patients in this series of cases.

Ten of the women had been married for periods of from 4 years to 25 years with an average of 11.1 years. Four were single. Two were separated from their husbands.

Symptoms All of the patients had complained of one or more symptoms for periods ranging from 2 months to 18 years with an average of 6.5 years. As will be shown in subsequent paragraphs many of these symptoms are related to the early stages in the development of the endometriosis. Those relative to the effects of intestinal invasion will be discussed first, as being most pertinent to the problem under investigation.

Four of the patients (all with sigmoidal lesions) were suffering from complete stoppage of the bowels at the time of initial examination. In this group the picture was typical of acute obstruction with lower abdominal pain abdominal distention and complete obstipation with no passage of feces or flatus. In an additional 6 cases the symptoms pointed to the existence of partial intestinal obstruction of rather severe degree but which allowed the passage of some gas through the point of narrowing. In 3 of these cases the sigmoid portion of the colon in 2 the rectosigmoidal junction and in 1 the distal portion of the ileum were respectively the sites of pathologic narrowing by the process. In the remaining 6 cases progressively severe constipation, constipation alternating with diarrhea, abdominal distention and other symptoms listed subsequently became progressively worse in an intermittent fashion and indicated the progression of gradual narrowing of the bowel. These we classified as cases of chronic obstruction. In 3 of these cases the sigmoid portion of the colon was the seat of the obstruction with the rectosigmoidal segment accounting for another and the distal portion of the ileum as the site of the remaining two lesions.

Considering the group as a whole moreover we find additionally that all 16 of the patients complained of cramping abdominal pain. Abdominal distention and severe constipation were prominent in all 10 cases falling into the first two groups listed in the preceding paragraph. Vomiting had occurred as a symptom in 1 of the 3 cases of obstructing endometriosis of the ileum and in 4 of the remainder.

Symptoms which might be attributed in part to the process in its preobstructive stage might be listed as intermittent constipation noted by 13 patients as being worse at the time of menstruation than at other times. Five of the patients had suffered from intermittent attacks of diarrhea and 4 of these had had alternating periods of constipation and diarrhea. Grossly bloody stools had been noticed by 3 patients. This symptom had been present only with menstruation. Four of the patients had sustained loss of weight in one case to the extent of 27 pounds (12.2 kg). It was felt that in these cases abdominal distress resulting from incipient obstruction had led to decreased dietary intake. An earlier group of symptoms are related more to the existence of pelvic endometriosis than to its intestinal complications and are herein mentioned to complete the picture on a chronic basis.

Infertility relative or absolute was frequently present and 9 of the patients complained of absolute sterility. The 10 married women in the series had had a total of but 3 pregnancies only 2 of which terminated with the birth of live children. One of the 4 unmarried patients had had a pregnancy which terminated in (or was terminated by) abortion. Among the 4 women who had been pregnant the average period which had elapsed since the last pregnancy was 14.2 years with extremes of 5 and 23 years. The importance of these findings is further emphasized by the fact that 6 of the 10 married patients mentioned had undergone previous pelvic operations designed in several instances to make pregnancy possible by resecting regions of endometriosis.

Acquired dysmenorrhea was a major symptom in 8 of the 16 cases. In an additional 4 cases the patients did not complain of this symptom. In the remaining 4 cases the rec-

ords did not supply information on this point. Dyspareunia, surprisingly enough was not listed as a major symptom by any patient in this group. It was elicited as not being a symptom in 2 cases and in the remainder the records were noninformative. However 5 of the 13 patients whose lesions were found in the lower segments of the bowel had complained of rectal pain and several others had complained of pain on defecation. Menstrual irregularities, so prominent in cases of pelvic endometriosis were noted in only 4 of the cases. In 9 the periods were described as being regular 2 patients had undergone previous hysterectomy and 1 patient had been amenorrheic for 3 years as a consequence of the menopause. Menorrhagia was noted as a symptom 4 times among the group and 2 patients having otherwise normal menses had complained of some intermenstrual spotting.

The aforementioned symptoms which were relevant to the underlying endometriosis rather than to its obstructive complication had been present for periods varying from several months to 18 years with an average duration of 6.5 years.

Physical findings in all 16 cases were consistent with the clinical diagnosis of intestinal obstruction. On the basis of an evaluation of symptoms combined with the results of digital rectal and vaginal examination the correct diagnosis was made preoperatively in 7 of the 16 cases studied.

Sigmoidoscopic examination was performed in 12 cases and in 9 of these positive evidence of luminal narrowing was obtained. In 2 cases as was proved later the sigmoidal lesions were beyond the reach of the sigmoidoscope and in the third case in which the findings were negative the lesion was located in the terminal portion of the ileum. In none of the cases was the presence of mucosal ulceration observed. In several cases however the sigmoidoscopist remarked on the peculiar puckering of the mucosa over the area of involvement.

In 9 of 11 cases results of roentgenographic study after administration of barium enemas were interpreted as being positive inasmuch as the roentgenograms demonstrated and localized the point of the obstruction. The

two failures were in a case in which the lesion was ileal and in another in which the upper portion of the rectum was only mildly obstructed by the endometrioma. By way of offsetting these 2 cases the roentgenologist in 2 of the less 'positive' examinations suggested the diagnosis of obstructing endometrioma.

TREATMENT¹

Fifteen of the 16 lesions were treated surgically by local resection of the bowel and in 1 instance partial excision of the endometrioma was accomplished. The details of the various procedures in the 16 cases follow

a When the point of obstruction was in the sigmoid or distal to it Resection of the bowel was done in 12 of the 13 cases in this group and in 1 the endometrioma was excised. In 5 of the cases complete resection of a segment of the bowel was done and in 1 case the resection of the bowel was partial. In this group of 12 resections of the bowel colostomy was performed 8 times and cecostomy was performed once. In 2 patients in their early thirties in this group myomectomy was performed plus resection of the bowel in a conservative effort to preserve reproductive function. Resection of the lower part of the bowel plus removal of both tubes and ovaries or of the remaining tube and ovary was done in 5 cases. Panhysterectomy plus resection of the bowel was done in 1 case and panhysterectomy plus partial excision of the endometrioma was done in 1 case.

b When the point of obstruction was in the distal portion of the ileum Enterostomy plus ileal resection was done in 1 case. An initial Witzel ileostomy and a subsequent right hemicolectomy and ileotransversostomy were done in 1 case. Ileal resection plus ileocecostomy and removal of the remaining tube and ovary were done in 1 case.

These patients had been followed up by examination and letters for from 1 month to 21 years. An excellent result with complete relief of the symptoms was obtained in 12

cases, a good result in 2 cases, and a fair result in 2 cases.

There were no deaths.

REPORT OF CASES

CASE 1 A single, white woman 43 years of age complained of symptoms fairly typical of partial obstruction of the small intestine of 3 months' duration. Physical examination revealed an emaciated weak woman who had abdominal distention and visible peristaltic waves. A roentgenogram of the colon was positive for obstruction of the small bowel. Medical treatment in the form of a double blood tube blood transfusions and supportive therapy was instituted. Complete obstruction occurred 1 week after admission. A Witzel type enterostomy was done and it was believed that ileocecal obstruction caused by a carcinoid existed. Four weeks later right colectomy was carried out with side-to-side ileocolostomy. No abnormality of endometrium was found in the pelvis. Pathologic examination revealed that the obstruction was caused by a deposit of endometrial tissue in the terminal portion of the ileum (Fig. 1).

CASE 2 A white woman 33 years of age who had been married for 9 years but had never been pregnant, complained of episodes of colicky lower abdominal pain of several months' duration. She had always been constipated. She suffered from severe acquired dysmenorrhea. Abdominopelvic examination showed tenderness and some rigidity in the right lower quadrant of the abdomen and an irregular, tender mass in the right adnexa. On abdominal exploration 3 small contracted and scarred regions were found in the terminal portion of the ileum. The middle region was producing partial obstruction of the terminal portion of the ileum. About 6 inches (15 cm.) of the ileum, including the three regions, was resected and an end-to-end anastomosis was made. The pathologist reported the process as one of multiple endometrioma of the ileum with partial intestinal obstruction. The patient made an uneventful recovery.

CASE 3 A white woman 32 years of age married for 10 years but never pregnant, complained of symptoms fairly typical of partial colonic obstruction which were present for 10 days prior to each menstrual period. She stated that 3 years previously myomectomy and left oophorectomy had been performed. Nine months prior to admission the symptoms of obstruction had begun to increase in severity. For 2 months obstruction had been almost complete.

Physical examination revealed a thin, malnourished woman. Pelvic examination indicated the presence of a large mass probably an ovarian cyst, in the right adnexa. Proctoscopic examination indicated this mass and the angulation of the bowel produced by it. Abdominal exploration was carried out for carcinoma of the sigmoid with obstruction. Because of the huge dilatation of the colon and

¹It is to be emphasized that most of the cases in the current series occurred before the time of the changing concept of treatment from that of resection of the bowel to that of bilateral oophorectomy. Present treatment consists in panhysterectomy plus conservative treatment of the bowel.

cecum proximal to the mass in the sigmoid and a large simple cyst of the right ovary oophorectomy and right salpingo-oophorectomy were done. Three weeks later resection of 20 centimeters of sigmoid which contained the mass together with a portion of the posterior uterine wall was carried out and an end-to-end anastomosis was made. The patient made a good recovery. Pathologic examination showed complete sigmoidal obstruction by the endometrioma.

CASE 4. A white single woman 31 years of age who had had 1 pregnancy which had ended in abortion complained of intermittent pain in the right lower quadrant of the abdomen of 9 years duration which occurred 1 week before during and after menses. The pain had been progressively increasing in severity and for the past month had been persistent without relief. Previous surgical treatment included appendectomy done 9 years before and left radical and right simple mastectomy done 3 years before for bilateral intraductal papillary carcinoma.

Abdominal examination revealed in the region of the cecum a peculiar ovoid flat tumor which was movable and tender. On exploration of the abdomen a region of endometriosis was found to be partially obstructing the terminal portion of the ileum. Right salpingo-oophorectomy and resection of the terminal portion of the ileum with ileocectomy and an end-to-side anastomosis were done. The patient made an uneventful recovery. The pathologist reported partial ileal obstruction by a region of infiltrating endometriosis.

CASE 5. A white married woman 54 years of age who had been pregnant once and was 3 years past the menopause complained of bleeding from the rectum and constipation—both of 18 months duration. Other symptoms of which she complained were excessive gas and occasional pain in the left lower abdominal quadrant which were relieved by repeated enemas. Rectal examination disclosed a carcinoma on the posterior rectal wall and biopsy showed this to be an adenocarcinoma, grade 1 (Broder's method). A roentgenogram of the colon revealed a partially obstructing lesion high in the sigmoid with occasional diverticula below this point. The carcinoma of the rectum was treated with radium and the patient returned in 3 months for an abdominal exploration. Marked obstruction of the midsigmoid by a lesion that grossly resembled endometriosis was found. An area of the sigmoid including the lesion was removed by an exteriorization operation by the clamp method. One month later radical posterior resection was done for the removal of a recurring adenocarcinoma of the rectum. The patient's recovery was uneventful. Pathologic examination of the specimen showed an endometrioma of the sigmoid which had caused almost complete obstruction.

CASE 6. A white woman 45 years of age who had had 1 child and was now separated from her husband complained of severe lower abdominal cramping

pain on the first 2 days of her period a sense of pressure in the lower part of her abdomen and sacral backache—all of 5 months duration. One year previously vaginal myomectomy dilatation and curet tage and perineorrhaphy had been performed. Metrorrhagia had been present for 5 weeks.

Pelvic examination showed marked cervicitis and erosion and a suspicious "precancerous" region on the posterior lip of the cervix. On abdominal exploration a nodule in the sigmoid causing almost complete obstruction was found. A first stage Mikulicz operation and panhysterectomy plus appendectomy were performed. About 2 weeks later a second stage Mikulicz operation was done and the colonic stoma was closed 4 months later. Recovery was good. The pathologist reported sigmoidal obstruction caused by endometriosis.

CASE 7. A white single woman 46 years of age complained of dull pain across the lower part of the abdomen and severe constipation of 5 years duration. She stated that 5½ years previously subtotal hysterectomy and left salpingo-oophorectomy had been performed and 5 years previously colostomy had been performed to relieve an acute sigmoidal obstruction caused by what was believed to be a malignant lesion.

Sigmoidoscopic examination revealed marked narrowing of the lumen of the sigmoid. The mucosa was intact and the narrowing appeared to be due to an extrarectal mass. On exploration of the abdomen a structured region just above the rectosigmoidal juncture was found. This region was resected and an end-to-end anastomosis was made over a rubber tube. Six months later the colonic stoma was closed. Pathologic examination of the specimen showed sigmoidal obstruction caused by an endometrioma.

CASE 8. A white woman 43 years of age, who had been married for 17 years without ever having become pregnant, complained of symptoms fairly typical of chronic intermittent partial intestinal obstruction of 12 years duration. She stated that appendectomy had been done 21 years previously, partial hysterectomy and right salpingo-oophorectomy had been done 14 years previously and hemorrhoidectomy 3 years previously.

Pelvic examination showed no uterine fundus and a fairly normal cervix. The roentgenogram of the colon showed a constriction high in a redundant sigmoid which was questionably caused by some extrinsic process. On abdominal exploration endometriosis was found involving the mesentery of the midsigmoid and almost completely encircling the intestinal lumen causing marked constriction in this region. An exteriorization operation with removal of the lesion and left salpingo-oophorectomy was accomplished. The patient made an uneventful recovery. The pathologist reported sigmoidal obstruction caused by a region of endometriosis which had practically encircled the sigmoid had deeply infiltrated the intestinal wall and had reduced the diameter of the lumen to 5 millimeters.

CASE 9. A white woman 41 years of age, who had been married for 12 years without becoming pregnant, complained of "comenstrual" constipation of 5 years duration. Three weeks prior to admission she presented symptoms that were fairly characteristic of colonic obstruction. Physical examination revealed that the uterus was somewhat fixed in the midposition by a thickened mass in the region of the left broad ligament and by nodules in the pouch of Douglas which via the vaginal speculum appeared blue-domed. A roentgenogram of the colon showed a lesion in the sigmoid which had completely obstructed the retrograde flow of barium. On abdominal exploration the pelvic mass was found to involve the posterior wall of the uterus and the sigmoid. Transverse colectomy was performed. One month later the lesion and a part of the midportion of the sigmoid were resected and an end-to-end anastomosis was made. The colonic stoma was closed later and a series of roentgen treatments over the adnexa was given to produce cessation of ovarian function. The patient made a good recovery. Pathologic examination showed sigmoidal obstruction caused by diffuse endometriosis of the sigmoid.

CASE 10. A single white woman 41 years of age complained of severe "comenstrual" constipation of 18 years duration and of symptoms fairly typical of chronic intermittent partial intestinal obstruction for the last few years. She stated that appendectomy had been done 13 years previously and unilateral salpingo-oophorectomy 1 year previously.

Physical examination showed a slightly enlarged uterus with a pedunculated egg-sized fibroid on its wall. Sigmoidoscopic examination revealed sharp anterior angulation of the bowel at 20 centimeters. A roentgenogram of the colon showed a long constricting obstructing lesion in the midsigmoid. The abdomen was explored and extraperitoneal resection of an endometrioma of the lower sigmoid was done with a catheter colectomy which was later closed. The patient made an uneventful recovery. The pathologist reported sigmoidal obstruction by a discrete endometrioma.

CASE 11. A white married woman 48 years of age who had never been pregnant complained of severe constipation and acquired menstrual pain. During menstruation she was obtunded for 1 or 2 days. Ten years previously she had undergone partial hysterectomy because of tumors and menorrhagia.

Physical examination revealed a hard mass filling the pouch of Douglas. Abdominal exploration was performed and, low down between the vaginal vault and the rectum a hard mass suggesting an endometrioma and causing definite obstruction was found. A portion of the bowel was resected and an end-to-end anastomosis plus appendicostomy was done. The patient made an uneventful recovery. Pathologic examination of the specimen revealed obstruction by a large endometrioma.

CASE 12. A white woman 38 years of age who had been married for 10 years without having become

pregnant complained of severe "comenstrual" constipation. Rectal "soreness and aural pain. Physical examination revealed a slightly irregular mass in the posterior fornix between the rectum and the vagina measuring 4 by 4 centimeters and protruding into the rectum. Sigmoidoscopic examination showed an anterior extrarectal mass at about 15 centimeters above the anus. Abdominal exploration revealed an endometrioma on the anterior wall of the sigmoid with definite obstruction. The anterior wall of the sigmoid with the tumor was resected and the bowel was closed transversely. Myomectomy, appendectomy and excision of other regions of endometriosis were accomplished. The patient made a good recovery. The pathologic specimen consisted of the resected endometrioma covered on one aspect by a layer of colonic mucosa.

CASE 13. A white married woman 45 years of age, who had never been pregnant, complained of "comenstrual" constipation and pain in the left lower quadrant of the abdomen of 4 years duration. Six months previously she had had symptoms fairly typical of acute intestinal obstruction and on abdominal exploration an obstructive lesion thought to be nonmalignant had been found in the rectosigmoidal region. Colectomy had been performed.

Physical examination revealed abdominal distention. A roentgenogram of the colon showed an irregular filling defect in the sigmoid near the colonic stoma. Sigmoidoscopic examination showed obstruction of the bowel at 24 centimeters as if by external pressure. Abdominal exploration showed a pelvic mass involving one loop of small intestine and a portion of the sigmoid. The loop of small intestine was mobilized and the portion of sigmoid resected. An end-to-end anastomosis was made. The patient's recovery was satisfactory and the colonic stoma was closed 1 month later. The pathologist reported sigmoidal obstruction by an infiltrating region of endometriosis.

CASE 14. A white woman aged 31 years, who was separated from her husband and who had had 1 pregnancy 5 years previously which had been terminated by a self-induced abortion complained of 4 to 5 loose stools with slight bleeding per day for 3 days premenstrually accompanied by intermittent cramping abdominal pain and later postmenstrual constipation—all of 6 months duration. She stated that 1 year after the aforementioned self-induced abortion dilatation and curettage had been performed because of menorrhagia, clots, and severe pelvic pain.

Physical examination demonstrated bilateral cystic adnexal masses and a firm mass in the pouch of Douglas which encroached on the anterior intestinal wall. Sigmoidoscopic examination showed adhesion of the anterior sigmoidal wall to an extrarectal mass, angulation of the bowel to the left, and marked luminal obstruction—all consistent with endometriosis. A roentgenogram of the colon showed fixation of the lower part of the sigmoid and luminal narrowing by an extrinsic process consistent

with endometriosis. Abdominal exploration revealed that the endometriosis was almost completely kinking the sigmoid and had attached it to the back of the cervix. Panhysterectomy appendectomy and biopsy of the endometrioma of the sigmoid were performed. Recovery was uneventful. The pathologist reported endometriosis of the sigmoid extensive endometriosis of the posterior surface of the uterus and bilateral chocolate ovarian cysts.

CASE 15 A white married woman 32 years of age who had never been pregnant, had previously complained of severe menstrual constipation and rectal pain. She stated that 2 years previously the left tube and ovary had been removed because of pain in the left lower abdominal quadrant. Five months previously symptoms consistent with complete colonic obstruction had developed. On exploration of the abdomen what was thought to be a malignant lesion had been found to be obstructing the lower part of the sigmoid. Colostomy had been performed.

Physical examination on admission showed nodularity of the uterosacral ligaments and an extra rectal mass behind and to the left of the cervix. Sigmoidoscopic examination revealed an anterior extra rectal mass at 18 centimeters which impinged on the lumen of the bowel. On abdominal exploration an endometrioma of the sigmoid which had caused obstruction was found. The involved portion of the sigmoid was firmly adherent to the cervix. The uterus, right tube and ovary and the portion of the sigmoid including the lesion were removed. End-to-end anastomosis was performed and also appendectomy. The colonic stoma was closed 7 months later. The pathologist reported that in the resected portion of the sigmoid there was a region of endometriosis 4 by 3 by 2 centimeters infiltrating into the sigmoidal wall and causing obstruction.

CASE 16 A white married woman 35 years of age who had never been pregnant, complained of diarrhea, gas, and abdominal colicky pain which were present on the first few days of menstruation. Ten months previously the patient had had an acute episode of lower abdominal colicky pain with vomiting and no bowel movement for 3 days. Previous surgical treatment had consisted of appendectomy done elsewhere and curettage done as a sterility study measure 1 year before.

Physical examination revealed an extrarectal nodular mass about 2 centimeters in diameter on the anterior rectal wall. Sigmoidoscopic examination showed at about 12 centimeters up on the anterior rectal wall an impinging region of induration about the size of a 5 cent piece and a roentgenogram of the colon showed a deformity of the sigmoid. Exploration of the abdomen showed that an endometrioma measuring about 1 1/4 inches (4 cm.) in diameter and situated at the bottom of the pouch of Douglas was causing almost complete obstruction of the sigmoid. A segment of the sigmoid containing the endometrioma was resected and an end-to-side anastomosis was established. The patient made an

uneventful recovery. Pathologic examination of the specimen showed the sigmoid doubled on itself with a large endometrioma in its midportion (Fig. 2). The obstruction had been caused by infiltration of the mass into the sigmoidal wall and compression of the sigmoid by the mass.

PATHOLOGIC OBSERVATIONS

Pertinent gross pathologic observations noted on the 15 resected lesions and the 1 partially excised lesion were as follows:

Nature Three sigmoidal lesions had produced obstruction by virtue of an annular or napkin ring type of infiltration with more or less concentric narrowing of the intestinal lumen. In 8 additional cases (2 lesions classified as high rectal and 6 as sigmoidal) the appearance was that of polypoid submucosal infiltration producing obturation of the intestinal lumen. In 2 other instances an eccentric cicatrization produced by infiltrating endometriomas had produced acute angulation while at the same time submucosal proliferation of the endometrial tissue gave a superadded factor of obturation. A combination of impingement and kinking from endometrial adhesions obtained in the 3 cases of ileal endometrioma with obstruction.

Size Gross limits of the infiltrations varied from 6 by 4 by 2 1/2 centimeters to 1 by 1 by 1 centimeters. The average dimensions were 2 1/2 centimeters in diameter with 7 of the endometriomas exceeding this size.

Color The dark red mottled appearance so characteristic of the lesions as seen at operation was replaced in the formalized specimens by the presence on the peritoneal and cut surfaces of scattered bluish spots on a whitish brown background of fibromuscular tissue. Some of the cut surfaces presented a striated appearance and from them tiny drops of brownish black fluid could be expressed by scraping with a knife.

Consistency mucosal serosal relations and so forth The involved tissues were nodular firm and fibrous without sharp delineation in the zones demarcating the edges of the infiltrations. In 9 instances the overlying mucosa was puckered in a roset fashion. In 6 it was irregularly pitted and in 1 case it presented an edematous polypoid appearance. Although no gross mucosal ulceration was noted in 11

TABLE 1.—POSITION OF THE ENDOMETRIAL GLANDS AND STROMA IN ENDOMETRIOMA OF THE BOWEL FROM THE CURRENT SERIES

Case	Segment of bowel	Submucosa		Muscularis		Serosa	
		Glands	Stroma	Glands	Stroma	Glands	Stroma

15	Rectosigmoid	+	+	+	+	+	+
16	Sigmoid	+	+	+	+	+	+

+ = positive 0 = negative — = not stated.

of the 16 cases the mucosa was more or less firmly adherent to the underlying submucosa and to the muscularis propria. Irregular puckering of the peritoneal coat was noted in all of the lesions.

Proximal segments. In all of the specimens in which accurate luminal dimensions could be studied the bowel proximal to the obstruction showed the effects of stasis in the form of dilatation (Fig 1). In 11 cases this degree of dilatation was estimated to be two or more times the luminal diameters distal to the endometriomas. This obstructive dilatation moreover was paralleled in a general way by increases in thickness of the muscularis propria. In 9 of the specimens this layer was approximately doubled in thickness.

Associated pathologic conditions. Uterine fibromyomas had been noted at operation or removed in 8 of the 16 cases. Six patients had extensive ovarian endometriosis with tarry cysts. Four patients had simple ovarian cysts and the ovaries and tubes of an additional 2 were involved in adhesions. If in addition we consider that 9 patients had pre-

viously undergone surgical exploration of the pelvis it becomes apparent that the obstruction of the bowel by endometriosis was but a part of the picture.

MICROSCOPIC FEATURES

In essence the intestinal lesions consisted in invasion by endometrial glands and stroma of the serosa, muscularis, submucosa, and mucosa in variable combinations (Table 1). Added to this was the important factor of reactive fibrosis with stenosis resulting from the contraction of maturing fibrous tissue. Since the process was fundamentally extrinsic in point of origin mucosal changes were the least frequently noted. In 4 instances the endometrial glands and stroma invaded the muscularis mucosae and in 1 of these a microscopic-sized area of ulceration involved the overlying epithelium. Considerable mucosal scarring was present. Infiltration of the submucosa obtained in 11 instances (Fig 3). All specimens showed infiltration of the muscularis propria. All 3 specimens of ileal endometriosis showed a major concentration of endometrial glands and stroma in the serosa and outer muscular coats. In contrast the sigmoidal and high rectal lesions were generally of the "deep" type—that is, the inner circular layer of muscle and the submucosa exhibited the greatest number of these ectopic elements. As a matter of fact in 5 cases of well circumscribed endometriosis of the sigmoid routine sections failed to reveal the presence of serosal endometriosis, although one certainly might concede that it had existed earlier in the course of the invasive process.

Although the proportion of endometrial glands to stroma varied a great deal (Fig 3), in general these elements were present in about equal proportions. The glandular and stromal elements were in all cases similar to their normal intrauterine counterparts and they exhibited pictures typifying all the phases of the menstrual cycle. Within the musculature of the bowel the endometrial glands seemed to proliferate in an axis parallel to that of the muscle bundles (Fig 4) as though the invading tissue were following the lines of least resistance rather than per-

Fig. 2 Gross specimen (Case 16) of sigmoid which is doubled on itself. Note the large endometrioma (5 by 5 by 3 cm.) in its midportion which has impinged on the intestinal lumen to obstruct it.

ing lymphatic spaces. The presence in 6 cases of cystic glandular hyperplasia was correlated with a clinical history of *menstrual irregularity* noted in the histories.

Studies made using the van Gieson stain for fibrous tissue revealed in all instances fibroblasts and collagenous fibrils around the nests of endometrial glands and stroma (Fig. 5). This fibrous tissue was occasionally hyalinized. In both the fibrous and the hyalinized examples this reaction tissue was seen to infiltrate the invading glands and stroma on the one hand and the invaded muscular tissues on the other.

Stains for iron demonstrated the presence of this substance in 5 instances only. This was something of a surprise since we had surmised that the concentration would obtain on the basis of a reaction to hemosiderin deposited during menstruation from the ectopic endometrium.

COMMENT

Endometriosis is the only common condition in which there occurs invasion of one tissue by another normal tissue of the same

host.^{1,2} When the bowel is the victim of this infiltrative process the segments affected are usually those which are situated in the pelvis. These are the sigmoid, the rectosigmoidal juncture, the rectum, and the distal portion of the ileum. As with endometriosis elsewhere the survival of the lesions is predicated on the influence of the cyclic hormonal stimulation of the ovaries. In the absence of this stimulation endometriosis undergoes retrogression. Endometriosis invades the intestinal wall from its serosal side and grows inward into the muscular layers and the submucosa (Fig. 6). Rarely may the mucosa of the bowel be invaded grossly (Fig. 7).

Sampson's implantation hypothesis plus Harbitz' idea of extraperitonealization will explain the pathogenesis of endometrioma of the sigmoid and ileum, while an equally good alternative hypothesis is that of lymphatic and venous metastasis (7, 31).

The frequency with which the diagnosis of endometriosis (35) is made by the clinician, the surgeon, or the pathologist varies with their threshold of suspicion, and it is our feeling that many cases have passed unrecog-

¹Traumatic rupture of the spleen is occasionally followed by a peritoneal seeding of splenic transplants.

²The placenta might be considered to be an exception, depending on the interpretation of the word "host."

Fig. 3 Sigmoid (Case 3) Endometrial glands and stroma are seen in the submucosa. Note variation between amount of glands and stroma present (hematoxylin and eosin $\times 57$)

Fig. 4 Sigmoid (Case 5) Note that the long axis of the muscle fibers runs parallel to the long axis of the endometrial glands (hematoxylin and eosin $\times 37$)

nized. The truth of this statement is also applicable to the complication of intestinal obstruction caused by endometriosis since against our series of 16 cases a "literature" of only 40 cases seems inadequate.

The symptoms of intestinal obstruction caused by endometriosis may be divided into two main groups: (1) the symptoms and signs of usually extensive pelvic endometriosis and (2) the symptoms and signs of intestinal obstruction in its various degrees.

Endometriosis occurs in women usually between the ages of 30 and 50 years. The majority of the women are sterile. More than half of the women have never been pregnant¹ and at least two-thirds have never carried a fetus through to full term delivery.

A periodicity of symptoms associated with the menstrual cycle and the onset of menstruation is the single most important sign of endometriosis *per se* and its complication of intestinal involvement. This periodicity of symptoms includes both the symptoms of

¹This too may depend on the physician "threshold of suspicion" in the search of the patient's past history.

Fig. 6 Sigmoid (Case 5) Endometrial glands and stroma are seen in the submucosa. Of significance is the fusion in a scarred area of the muscularis mucosae and propria (hematoxylin and eosin $\times 70$)

Fig. 7 Sigmoid (Case 8) Note ulceration of the mucosa (rare and not characteristic) and the presence of endometrial glands and stroma. The muscularis mucosae is thickened and fibrosed (hematoxylin and eosin $\times 70$)

endometriosis and those of intestinal obstruction. A history of the symptoms of acquired dysmenorrhea, rectal pain associated with or between defecations, sacral pain or deep pelvic pain or discomfort (which may extend down into the thighs and is made worse by jarring), severe constipation or diarrhea, and dyspareunia that are increased just before during or just after menstruation is usually indicative of extensive endometrial involvement of the sigmoid, rectosigmoidal juncture or rectum. When these symptoms become progressively worse and lengthen out in duration premenstrually, postmenstrually or both, obstructive intestinal symptoms are usually imminent.

The symptoms of intestinal obstruction then become superimposed on those of endometriosis of the bowel at first usually only comenstrually. These symptoms for the sigmoid and below are those of lower abdominal pain (which is one of the first to be present) along with abdominal distention and finally obstipation which may be present for only 1

or 2 days during the period. When the sigmoid or more distal portions of the bowel are obstructed, nausea and vomiting usually occur late because of the competence of the ileocecal valve (45). Occasionally a reflex type of nausea and vomiting may be encountered. The symptoms of the endometriosis plus the superimposed symptoms of the intestinal obstruction which at first are mild, become progressively worse, lengthen out premenstrually or postmenstrually and either go on to the production of acute complete or partial obstruction at one of the menstrual periods or assume the form of chronic intermittent partial obstruction of high or low grade.

Compared with intestinal obstruction in general caused by endometriosis, ileal obstruction caused by endometriosis more often occurs among younger women who usually have less extensive pelvic involvement by endometriosis or sometimes no other grossly visible pelvic involvement. These patients may or may not have the general symptoms of endometriosis but when these symptoms are

A roentgenologic examination of the colon is assuming a rôle of importance in the diagnosis of endometriosis causing intestinal obstruction. If the obstruction is complete the employment of a roentgenogram of the colon may accurately localize the lesion. If the obstruction is incomplete the proper interpretation of the roentgenogram of the colon may not only localize the obstructing lesion but identify the cause as endometriosis as well. The characteristic lesion on roentgenologic examination of the colon is said to be a long inconstant filling defect with sharp regular borders intact mucosa and fixation of the bowel which is very tender to palpation.

Diagnosis. The diagnosis of intestinal obstruction which has been caused by endometriosis or endometrioma may best be made by first obtaining an accurate history of the development of the symptoms which are diagnostic of endometriosis. Points of importance are as follows: (1) a woman in the reproductive period of life, usually between the ages of 30 and 50 years; (2) who is in fairly good general health and has not lost weight; (3) who suffers from absolute relative or secondary sterility or who has married late or has not been pregnant for some time; (4) who has acquired dysmenorrhea; and (5) who has a history of usually a year or longer of symptoms which occur with menstrual periodicity: (6) symptoms such as severe constipation, rectalgia or dyschezia, dyspareunia, occasionally diarrhea, and rarely rectal bleeding; (7) low deep pelvic discomfort caused by jarring of the body; (8) sacral backache which may run down into the thigh; and (9) symptoms of intestinal obstruction such as lower abdominal cramping colicky pain, abdominal distention and obstipation or vomiting or both which have shown menstrual periodicity and become progressively more severe.

These symptoms plus the finding of (1) on pelvic examination tender nodules in the pouch of Douglas or a large tumor of the rectovaginal septum and associated uterine fibroids and bilateral ovarian cysts; and (2) a sigmoidoscopic examination that shows an intact puckered mucosa and a stenosed or narrowed intestinal lumen from an extrarectal mass; or (3) a roentgenogram of the colon that shows a

Fig. 9. Sigmoid (Case 16). Note the large cyst in the submucosa and the invasion of the submucosa and muscular layers by endometrial glands and stroma in the late differentiative phase (hematoxylin and eosin $\times 9$).

long inconstant filling defect with regular borders intact mucosa and fixation of a tender bowel indicate a highly presumptive diagnosis of intestinal obstruction caused by endometriosis. Positive diagnosis can be made only by operation and surgical biopsy of the lesion with frozen section and microscopic pathologic confirmation.

Treatment. 1. Surgical treatment.—The treatment of intestinal obstruction caused by endometriosis is surgical. The basic principle in the treatment of this condition is the fact that retrogression of endometriosis depends on the absence of ovarian hormonal stimulation. Hence to treat the patient the surgeon may elect usually to remove both ovaries¹ (as pointed out by Milnor and others) or occasionally to resect the bowel (30) or in rare instances to do both. Factors to be considered by the surgeon are the age of the patient, her desire to become pregnant, the probability of

Radiation castration could not be expected to produce rapid regression of the obstructing intestinal lesion. Surgical castration alone on the other hand is often followed promptly by the relieving of serious obstructive symptoms.

Fig. 8. Sigmoid (Case). Note the island of endometrial glands and stroma, the late differentiative phase of the subserosa (hematoxylin and eosin $\times 66$).

present it is usually to a lesser degree. This is represented by the facts that the group with ileal involvement had a higher fertility rate, fewer previous pelvic operations, fewer uterine fibroids and a lesser incidence of associated pelvic pathologic changes. Also in the ileal group no patient had rectal pain, constipation was less frequent, only 1 patient complained of diarrhea and no patient had blood in the stools. Vomiting was a more frequent symptom than obstipation.

Often according to the literature, and once in the current series, obstruction of the distal portion of the ileum by endometriosis has been diagnosed clinically as appendicitis accompanied by paralytic ileus. If however the history is taken carefully the symptoms of the endometriosis are usually elicited. Definite symptoms of low ileal obstruction are superimposed on the periodic menstrual symptoms of acquired dysmenorrhea, constipation and so forth.

Gross blood in the stools is usually not an important symptom of endometriosis of the bowel. It is of significance only when other

anorectal lesions have been excluded and when it is present only at the menstrual period.

Valuable adjuncts to the symptoms in the diagnosis of intestinal obstruction as caused by endometriosis are digital examination of the vagina and rectum, the sigmoidoscope and roentgenographic examination of the colon and the terminal portion of the ileum after administration of a barium enema.

Pelvic examination most often reveals tender palpable nodules in the rectovaginal septum or the pouch of Douglas, frequently the presence of associated uterine fibroids and in many cases the presence of ovarian cysts, usually bilateral. On operation these are most often observed to be the chocolate cysts of endometriosis. Pelvic examination is best made just before or during menstruation because of increased tenderness and congestion. If a discrete endometrioma is present in the rectovaginal septum it may be palpated. A thorough search of the vaginal vault via a speculum at the time of menstruation may reveal the presence of the purplish pink lesions of endometriosis which have invaded the vaginal wall. The vaginal wall may sometimes be invaded but the rectal mucosa almost never is.

On sigmoidoscopic examination there is rarely gross bleeding and almost never gross ulceration. The positive findings will be those of a greatly narrowed lumen, an anterior extrarectal mass, acute angulation of the bowel and mucosal puckering and congestion. The appearance is much like that of obstructing diverticulitis and cannot be positively differentiated from it by means of the sigmoidoscope but the intact mucosa differentiates it from carcinoma. Biopsy of the intestinal mucosa is usually not practical for since the mucosa is not extensively involved the report will usually come back negative or "inflammatory change only." Even in the few cases in which rectal bleeding has been a symptom the mucosa has appeared only puckered or adherent but not ulcerated and fairly normal. It is important to remember that carcinoma invades the intestinal wall from the mucosa outward while endometriosis invades it from the serosa inward.

A roentgenologic examination of the colon is assuming a rôle of importance in the diagnosis of endometriosis causing intestinal obstruction. If the obstruction is complete the employment of a roentgenogram of the colon may accurately localize the lesion. If the obstruction is incomplete the proper interpretation of the roentgenogram of the colon may not only localize the obstructing lesion but identify the cause as endometriosis as well. The characteristic lesion on roentgenologic examination of the colon is said to be a long inconstant filling defect with sharp regular borders intact mucosa and fixation of the bowel which is very tender to palpation.

Diagnosis The diagnosis of intestinal obstruction which has been caused by endometriosis or endometrioma may best be made by first obtaining an accurate history of the development of the symptoms which are diagnostic of endometriosis. Points of importance are as follows: (1) a woman in the reproductive period of life usually between the ages of 30 and 50 years; (2) who is in fairly good general health and has not lost weight; (3) who suffers from absolute relative or secondary sterility or who has married late or has not been pregnant for some time; (4) who has acquired dysmenorrhea; and (5) who has a history of usually a year or longer of symptoms which occur with menstrual periodicity; (6) symptoms, such as severe constipation, rectalgia or dyschezia, dyspareunia, occasionally diarrhea and rarely rectal bleeding; (7) low deep pelvic discomfort caused by jarring of the body; (8) sacral backache which may run down into the thigh; and (9) symptoms of intestinal obstruction such as lower abdominal cramping, colicky pain, abdominal distention and obstipation or vomiting or both which have shown menstrual periodicity and become progressively more severe.

These symptoms plus the finding of (1) on pelvic examination tender nodules in the pouch of Douglas or a large tumor of the rectovaginal septum and associated uterine fibroids and bilateral ovarian cysts; and (2) a sigmoidoscopic examination that shows an intact puckered mucosa and a stenosed or narrowed intestinal lumen from an extrarectal mass; or (3) a roentgenogram of the colon that shows a

long inconstant filling defect with regular borders intact mucosa and fixation of a tender bowel indicate a highly presumptive diagnosis of intestinal obstruction caused by endometriosis. Positive diagnosis can be made only by operation and surgical biopsy of the lesion with frozen section and microscopic pathologic confirmation.

Treatment 1. Surgical treatment.—The treatment of intestinal obstruction caused by endometriosis is surgical. The basic principle in the treatment of this condition is the fact that retrogression of endometriosis depends on the absence of ovarian hormonal stimulation. Hence to treat the patient the surgeon may elect usually to remove both ovaries¹ (as pointed out by Milnor and others) or occasionally to resect the bowel (30) or in rare instances to do both. Factors to be considered by the surgeon are the age of the patient, her desire to become pregnant, the probability of

Radiation castration could not be expected to produce rapid regression of the obstructing intestinal lesion. Surgical castration alone on the other hand is often followed promptly by relieving of serious obstructive symptoms.

her becoming pregnant, the existence of associated pelvic pathologic lesions and the location and extent of the endometriosis together with the degree of intestinal obstruction present. Decision to do a conservative operation implies that the surgeon must be sure that the intestinal lesion is *not* in fact a carcinoma.¹ Because the treatment of intestinal obstruction varies with the location of the lesion the therapy of colonic obstruction will be discussed first followed by that of ileal obstruction.

a Treatment when the point of obstruction is in the sigmoid rectosigmoidal junction or rectum.—In these cases the involvement of the pelvis and colon by endometriosis is usually extensive and bilateral oophorectomy or panhysterectomy is usually indicated. Panhysterectomy is justified because the endometrioma of the colon will retrogress the obstruction will be relieved and associated pelvic lesions, which are nearly always present will be removed. If the obstruction is complete or incomplete with much dilatation of the proximal portion of the bowel temporary proximal colostomy should also be done to decompress the bowel. The stoma may be closed in a few months after subsidence of the endometrioma. If the patient is a young woman who is desirous of a pregnancy and whose pelvic organs are essentially normal resection of the involved segment of the bowel is the procedure of choice.

b Treatment when the point of obstruction is in the ileum.—In these cases the treatment of choice is resection of the bowel or if the diagnosis is apparent to the surgeon a short-circuiting procedure. The obstruction in these cases is to some degree caused by the partial occlusion of the lumen by the endometrioma but more by the tough dense adhesions of endometriosis and resultant kinking of the bowel.

2 Surgical treatment versus roentgen therapy.—Roentgen therapy should be reserved for those patients who are extremely poor operative risks or who have had intestinal recurrence of endometriosis following operations in which conservative treatment was given to the ovaries.

¹Chiefly among cases found early in our series, the surgeon felt reasonably certain that the intestinal lesion was malignant.

Presumable relationship of endometriosis to carcinoma. The question whether carcinoma may develop from endometriosis or on the basis of it has been much debated (p. 42). It is our conclusion that a *presumable* relationship may exist but there is no definite *factual* proof of it.

SUMMARY AND CONCLUSIONS

1 An analytic study of clinical data on it from the current series of cases of intestinal obstruction caused by endometriosis has been presented as well as the results of a pathologic study of these cases.

2 To make the diagnosis of endometriosis as a cause of intestinal obstruction, the possibility of its occurrence should be kept in mind in every case of intestinal obstruction in which the patient is a woman from 30 to 50 years of age. Acquired dysmenorrhea, menstrual periodicity of symptoms, sterility, rectal or pelvic pain, absence of loss of weight, the presence of associated uterine fibroids or ovarian cysts, and a long history of intestinal symptoms which suggest progressive intestinal obstruction with frequent exacerbations at menstruation are most important points in the diagnosis of this condition.

3 Severe constipation, lower abdominal pain and distention are almost always present. If the obstruction is ileal vomiting is almost always present while if the obstruction is colonic obstipation is more often present. Diarrhea is occasionally a symptom but the presence of gross blood in the stool in the absence of other anorectal disorders is very infrequent. If present at the time of menstruation it is of significance.

4 The symptoms of menorrhagia and metrorrhagia are not the symptoms of endometriosis *per se* but rather the symptoms of associated pelvic pathologic lesions.

5 An accurate preoperative diagnosis of intestinal obstruction caused by endometriosis can usually be made on the basis of the clinical history, digital examination, sigmoidoscopic examination and careful interpretation of the roentgenogram of the colon and the terminal portion of the ileum. The finding of a firm tumor in the rectovaginal septum or of tender palpable nodules plus the

palpation of uterine fibroids and bilateral ovarian cysts is suggestive of endometriosis as the cause when intestinal obstruction is present. Sigmoidoscopic examination with the presence of an extrarectal mass and an intact puckered mucosa and a roentgenogram of the colon with the presence of a long in constant filling defect with sharp regular borders and an intact mucosa are the two most valuable adjuncts to diagnosis when the lesion is in the lower bowel.

6. Surgical biopsy of tissue from the vaginal vault if the endometrioma is in the rectovaginal septum and has invaded the vaginal mucosa may afford pathologic confirmation of the clinical diagnosis but biopsy of the rectal mucosa is usually noninformative as the tissue in all the cases in which this was done in the current series was reported as inflammatory.

7. Obstruction of the ileum as caused by endometriosis presents a less characteristic clinical picture than that in the sigmoid or below.

8. The treatment of intestinal obstruction caused by endometriosis is surgical. A preoperative diagnosis of endometriosis as a cause of colonic obstruction will obviate the necessity for resection of the bowel in most instances and surgical treatment will consist usually of bilateral oophorectomy or of partial hysterectomy with or without temporary colostomy as is deemed necessary. The procedure of choice in obstruction of the ileum caused by endometriosis is ileal resection with or without preliminary enterostomy and with or without panhysterectomy as indicated by the presence and degree of associated pelvic pathologic lesions.

9. The mechanism of ileal obstruction was usually due to kinking caused by the endometriosis, while the obstruction in the sigmoid and below was more often due to an impingement of the endometrioma into the intestinal lumen.

10. If the patient is a young woman who has a discrete endometrioma of the ileum or sigmoid causing intestinal obstruction if the pelvic organs are essentially normal to the extent that there appears to be a reasonable chance of an ensuing pregnancy and if the

absence of menorrhagia or cystic endometrium has indicated evidence of fair ovarian function a conservative operation should be done as regards the ovaries and a radical operation done as regards the obstructed bowel. In intestinal resection without oophorectomy is indicated.

11. Microscopically endometrial glands and stroma were found in all layers of the intestinal wall (Figs 8 and 9). They seemed to be most diffusely dispersed in the muscular layers. The endometriomas of the sigmoid were of the discrete or deep type while the endometriomas of the ileum were located closer to the serosa.

12. Gross blood had been present in the stools of only 3 of 16 patients. The intestinal mucosa on gross inspection was intact in all cases but on microscopic examination it was invaded by endometriosis in 2 cases. In 1 of these cases microscopic ulceration had occurred.

13. Fibrosis around the endometrial glands and stroma was characteristic in all of the sections but a positive iron stain representative of hemosiderin was not characteristic. The muscle fibers in most instances seemed to run in the same long axis as that of the endometrial glands.

14. A plea is made for biopsy, frozen section and pathologic confirmation of the clinical diagnosis in all cases of endometrioma obstructing the bowel as carcinoma can be positively excluded only by this method. The prognosis of patients who have had intestinal obstruction caused by endometriosis is excellent and the surgical mortality rate was nil in the current series.

FRACTURES OF THE TIBIAL CONDYLES INVOLVING THE KNEE JOINT

EDWIN F. CAVE, M.D. F.A.C.S., Boston, Massachusetts

AN increasing agreement prevails among bone and joint surgeons that fractures involving joints especially weight bearing joints should be restored to normal anatomical relationship as accurately as possible and if necessary by surgical measures. This viewpoint applies particularly to fractures of the tibial condyles involving the knee joint. There are some authors who believe that for the most part these fractures can be handled reasonably satisfactorily by manipulative measures. Watson Jones would operate upon only the severely displaced condyles and would treat the majority of these fractures by manipulation. He has emphasized the likelihood of a poor result following any form of treatment of many of the badly comminuted fractures of the tibial condyles. E. M. Bick reported good functional results in 61 cases following nonoperative treatment. The majority of writers however Foged Leadbetter and Hand Buckner Ronald Palmer Barr and Knight believe that the fractures of the tibial condyles with any degree of displacement particularly the "bumper" fracture of the lateral tibial condyle are best treated by open reduction and internal fixation.

At the Massachusetts General Hospital from which this series of cases is reported we believe that like any other type of fracture each fracture must be evaluated as an entity and treated accordingly. Those fractures with little or no displacement can usually be handled by conservative measures namely manipulation followed by fixation or traction while many of those with gross displacement and separation and depression of the tibial condyles had best be operated upon but only by a skilled surgeon trained in meticulous joint surgery.

The commonest most difficult to handle and consequently the most important fracture involving the tibial condyles is the "bumper

or fender fracture which produces major damage to the lateral tibial table with or without damage to the external semilunar cartilage the internal lateral ligament and the cruciate ligaments (Fig 1). This fracture is practically always sustained by a force which sharply adducts and flexes the knee and in so doing compresses the external semilunar cartilage strains or tears the internal lateral ligament or the cruciate ligaments or both and at the same time depending on the severity of the force impacts the lateral femoral condyle against the lateral tibial condyle producing a compression fracture of the lateral tibial condyle which in many cases is severely comminuted. The maximum compression of the tibial condyle may be posterior to the midline because the most prominent curve of the femoral condyle occurs at this point.

In our cases the following were some of the causes of this type of fracture a blow by the bumper or fender of an automobile on the outer side of the knee a fall from a ladder landing with the knee flexed and adducted a blow on outer side of the knee from a charging steer in one case a large dog in another. In all adduction and flexion of the knee were involved and in all cases too there were varying degrees of injury and subsequent reaction in the joint.

While fracture of the lateral condyle is the commonest injury involving the tibial condyles others may occur depending upon the mechanism of injury. If the blow is received on the inner side of the knee fracture of the medial tibial condyle may occur with injury to the internal semilunar cartilage and to the external collateral ligament of the knee as occurred in the following case a young man of 21 while attempting to bulldog a steer was apparently struck on the inner aspect of the knee. There was immediate pain and disability and when the patient was seen 5 days later roentgenograms revealed a separation and de-

Fig. 1. Mechanism of injury in various types of tibial plateau fractures. Flexion and adduction of knee—strain of internal lateral ligament and compression of external semilunar cartilage. 2 and 3, Flexion and adduction of knee—injury to internal lateral ligament and probably cruciate ligaments. With compression of external semilunar cartilage and comminuted fracture of the lateral tibial condyle. 4, In addition to injuries 2 and 3, there is also fracture of the fibula head. 5 and 6, Bursting fracture of both condyles, usually sustained by fall from a height. 7 and 8, Flexion and abduction of knee—injury to external lateral ligament and probably cruciate ligaments—also injury to internal semilunar cartilage and comminuted fractures of internal tibial condyle.

pression of the medial tibial condyle. No attempt was made to manipulate this fracture but 7 days after injury the internal tibial condyle was replaced to its normal position and held with a tibial bolt. The end result was a knee which allowed the patient to drive an ambulance during most of the war. The knee was stable, had good alignment, with complete extension and flexion to 100 degrees.

Bursting fractures of both condyles may occur from very severe trauma either from a heavy blow or from falls from a great height. It is questionable whether this type of severely comminuted fracture can be sufficiently restored to justify open operation and our belief is that these markedly comminuted ones possibly should be treated with gentle manip-

ulation attempting to compress the fragments into more normal alignment with the hands of the operator or by specially devised clamps. Such compression clamps cannot be used without danger and not infrequently when operating upon tibial plateau fractures which have been unsuccessfully treated by using the clamp we have found that more comminution of the fracture has been produced and fragments of articular cartilage and semilunar cartilage had been compressed further into the tibial head. If manipulation and compression are used they should be followed by skeletal traction in the form of a Kirschner wire through the os calcis or lower end of tibia (Fig. 2). No matter what treatment is applied to these severely comminuted fractures, it is like-

Fig. 2. Anteroposterior and lateral views before and after treatment of a bursting fracture involving both tibial condyles and the upper tibial shaft. This type of fracture is best treated by gentle molding with the hands of the

operator and skeletal traction (Kirschner wire through os calcis) for 6 or 8 weeks followed by immobilization in plaster for 6 weeks and walking with crutches for 4 or 5 months after injury. Open reduction is contraindicated.

ly that some patients will eventually develop extensive traumatic changes resulting in arthritis of varying degrees. In such cases the wearing of permanent external support or an arthrodesis of the knee are probabilities.

In discussing pathological findings, symptoms and signs and x-ray findings we shall describe particularly the "bumper fracture" because it is the classical fracture involving the tibial condyles.

PATHOLOGICAL FINDINGS

There is immediate swelling of the joint due to hemorrhage and increased synovial fluid. Fat droplets will be present in the fluid if the fracture involves the subchondral area. The swelling will increase for 24 or 48 hours. There is always more or less damage to the internal lateral and cruciate ligaments and compression usually of the lateral tibial table and not infrequently also the fibular head. The degree of comminution, depression and separation of the fragments varies. More often than not the lateral semilunar cartilage is injured and may be displaced downward into the spongy bone of the main fracture line along with fragments of the articular cartilage of the central portion of the lateral condyle. In the most severe cases actual subluxation of the knee joint due to the extensive ligamentous injury may be present.

SYMPTOMS AND SIGNS

Pain is most marked on the inner aspect of the knee due to the unusually severe injury to the internal lateral ligament chiefly at its femoral attachment. If the degree of fracture is not great the patient may walk with assistance but if the depression of the lateral condyle is marked there will be complete disability. The knee will be held in a position of protection of 25 to 50 degrees of flexion and more or less knock knee position depending upon the degree of depression of the lateral tibial condyle. All active and passive motions will be severely painful and palpation will reveal marked joint line tenderness and particularly severe at the femoral attachment of the internal lateral ligament. Damage to the popliteal structures and the peroneal nerve is rare but should always be suspected.

X-RAY STUDIES

Roentgenograms of both knees should be taken in the same relative position with an anteroposterior, lateral and oblique views. If the injured knee is held in a position of flexion the normal knee should be roentgenographed in the same position. Little knowledge is gained from the lateral views while the anteroposterior and oblique views will reveal the diagnosis. Because of the soft tissue swelling

Fig. 3. Technique of operation

more than the usual x ray penetration should be used to demonstrate the fracture lines.

TREATMENT

For the severely depressed fracture of the lateral condyle it is difficult for us to see how such a fracture can be replaced by manipulative means with any degree of accuracy. Therefore we usually employ the following operation (Fig. 3). The lateral aspect of the knee is exposed with a bayonet incision beginning just posterior to the lateral femoral epicondyle about 3 inches above the joint line and curving forward at the joint line and down along the lateral portion of the tibial crest for 4 inches. The joint is opened anterior to the external lateral ligament with a curved in-

cision and posterior to the ligament and popliteus tendon with a perpendicular incision. The upper tibia is exposed subperiosteally back to the tibiohular ligament. Usually the semilunar cartilage is displaced downward into the fracture line and therefore it must be removed in order to visualize the fracture and also to effect reduction. The displaced lateral portion of the tibial table is osteotomized and turned outward and the depressed fragments elevated to their normal position. It may be necessary to remove some of the small fragments of articular cartilage which have little chance of survival. The main lateral fragment or fragments are then apposed to the tibia and secured by a long bolt with a tap on the inner end to maintain reduction. We must admit

Fig. 4. Preoperative and postoperative views of a typical "bumper" or depressed fracture of the lateral tibial condyle. The external semilunar cartilage which was depressed into the main fracture line was removed the

depressed "central" fragments were elevated and held in position with a graft which was taken from the lateral tibial crest, and the fractures were stabilized with a bolt and screw.

that extensive comminution of the fracture makes the procedure difficult. If this is the case a tibial bone graft removed from the anterior portion may be driven under the joint surface to preserve the tibial plateau (Fig. 4). We have not found it necessary to suture any of the internal lateral ligaments nor would we advise attempting to repair damaged cruciate ligaments at the time of reduction of the fracture. In only one case in our series was there severe damage to the cruciate ligaments which resulted in luxation of the knee and a poor functional result was obtained because of instability of the joint in spite of the fact that the fracture was well reduced by operation. If the mesial condyle rather than the lateral has been displaced the bayonet incision must be placed on the inner aspect of the knee in which case care should be exercised to preserve the internal saphenous nerve.

Whether plaster immobilization or suspension in a hinged splint should be used after operation is optional. We believe that if the fracture or fractures have been well stabilized by the bolt suspension is sufficient. Early exercises can be carried out in the splint and at the end of a 6 weeks period the patient is allowed up on crutches and with little weight bearing in a light hinged brace to prevent any tendency to valgus deformity of the knee.

If the fracture is a simple not comminuted one it is possible that manipulation and com-

pression followed by plaster will be sufficient for the minor displacements or depressions or both manipulation and plaster fixation may improve the situation. As in all fractures of weight bearing joints delayed weight bearing must be practiced. Crutches must be used for a period of 2 to 6 months depending upon the severity of the injury. Any tendency to valgus position of the knee must be prevented by the use of a hinged brace and Thomas heel.

ANALYSIS OF CASES FROM THE MASSACHUSETTS GENERAL HOSPITAL

From 1930 to 1945 inclusive we treated in our clinic a total of 69 fractures of the tibial condyles involving the knee joint. An earlier series of 29 cases from 1923 to 1930 was reported by Barr (10) in the Massachusetts General Hospital Fracture Book making a total of 98 cases.

In the 1923 to 1930 series of 22 end result cases 17 were treated by nonoperative means and only 5 by surgery, one operation being an arthrodesis for painful traumatic arthritis and 2 were compound fractures and simply debrided thus leaving only 2 simple fractures treated by open reduction and internal fixation. In the more recent series 1930 to 1945 40 patients were treated by nonoperative means and 29 were subjected to surgery. Many of the 40 patients in the nonoperative group presented minor fractures with a clinical pic-

ture of ligamentous strain only and did not require prolonged treatment. Of the 29 operative cases in the latter series 16 were male and 13 female with an average age of 47 years. Table I shows types of injury in the 29 cases.

Of the 29 cases 22 were simple fresh fractures suitable for open reduction and internal fixation. We add to these 2 similar cases from the 1923 to 1930 series making a total of 24 (Table II).

In comparing the two series of cases it is obvious that there has been an increasing tendency in our clinic to treat displaced fractures of the tibial condyles by surgical means. This has happened for 2 reasons (1) we believe that most of these fractures cannot be reduced by manipulation and (2) the improvement in operative technique by members of the Fracture Clinic during the past 10 or 15 years.

We are still not satisfied with some of our anatomical repositions. These partial failures have been due to the inexperience of some of the operators and to the severe comminution of some of the fractures. In the 1923 to 1930 series of 2 operative cases both patients obtained excellent results and were rated A 4 E-4 F 4. In the 22 patients operated upon in

1930 to 1945 21 were restored to their former economic status and 18 had acceptable results, from an anatomical and functional standpoint.

CONCLUSIONS

1. Many fractures of the tibial condyles with more than a moderate degree of displacement should be treated by open reduction and internal fixation.

2. The surgeon undertaking such an operation must be well trained in meticulous joint surgery.

3. Preliminary manipulation and compression of many fractures of the lateral and medial tibial condyles may do harm to the joint surface of the tibia and make the subsequent open reduction more difficult.

4. Extensive comminuted fractures involving both tibial condyles may not be successfully reduced either by closed manipulation or open reduction.

These conclusions are based on a study of 98 cases, of which 24 patients were treated by open reduction and internal fixation.

THE SURGICAL TREATMENT OF RECURRENT ACUTE PANCREATITIS BY ENDOCHOLEDOCHAL SPHINCTEROTOMY

HENRY DOUBILET M.D., F.A.C.S. and JOHN H. MULHOLLAND M.D. F.A.C.S.,
New York New York

SURGICAL treatment of acute pancreatitis and especially of recurrent acute pancreatitis has been essentially palliative. Since 1901 when Opie focussed the attention of surgeons on the observation that acute pancreatitis could be produced by retrojection of bile into the pancreatic duct when the ampulla of Vater was occluded by a stone the investigations of many surgeons and physiologists have been directed toward this problem. The operation of cholecystostomy or choledochostomy is but a temporary expedient to reduce the possibility of further passage of bile into an organ in which the disease process had already reached its apogee. The removal of stones from the gall bladder and bile ducts in recurrent pancreatitis and the prolonged drainage of the biliary tract are intended to be preventative measures and are so when obstruction at the ampulla is due to stone. Cholecystectomy in the absence of stones was advocated by Judd (20) and others for three reasons: (1) the removal of a muscular organ would prevent the forceful propulsion of concentrated bile into the pancreatic duct; (2) the absence of concentrated gall bladder bile would diminish the severity of its necrotizing action since the severity of the process was shown by Flexner to depend partly on the bile salt concentration and (3) cholecystectomy often resulted in relative atony of the sphincter of Oddi as noted by others (9, 21). That this concept of Judd was justified was confirmed experimentally by Wangenstein on cats. Under his experimental conditions the incidence of acute pancreatitis was reduced 50 per cent by cholecystectomy.

However in all these operative procedures since the essential anatomy, a common pas-

sageway between the choledochus and the pancreatic duct remains unchanged it is obvious that the possibility of further obstruction due to factors other than stone might be anticipated. The recurrence of pancreatitis in patients after these operations confirms this fact.

The probability that attacks of acute pancreatitis might recur following the successful treatment of concomitant biliary tract disease was emphasized by the finding that in about 50 per cent of all cases of acute pancreatitis the biliary tract was found to be normal. A solution of this puzzle was furnished by Archibald who suggested in 1913 (1) that spasm of the sphincter of Oddi might produce sufficient temporary obstruction to enable bile to enter the pancreatic duct. He proved his case in 1919 (2) producing acute pancreatitis in cats by injecting bile into the biliary tract while temporary spasm of the sphincter was being induced by mechanical and chemical measures. Recent cholangiographic and kymographic studies on patients have confirmed his opinion that the human sphincter of Oddi was a highly labile muscle. Spasm of this muscle was occasionally found postoperatively (14, 16). Such drugs as morphine, local application of irritants such as hydrochloric acid and even the response to emotional stimuli could produce spasm of the sphincter in the human (Figs. 1, 2, 3). Further as a result of this spasm either found incidentally or produced by pain or drugs, lipiodol or other radio-opaque substances could be seen in cholangiographic studies to enter the pancreatic duct (Figs. 4, 5, 6, 7) when it joined the bile duct above the sphincter of Oddi.

Obviously if obstruction at the ampulla of Vater by spasm converts the bile and pancreatic ducts into a common channel leading to

From the Department of Surgery, New York University College of Medicine.

Fig. 1. Effect of morphine on the sphincter of Oddi. Kymographic tracing of the resistance of the human sphincter of Oddi shows that following the administration of $\frac{3}{6}$ grain of morphine the normal resistance of the sphincter (50 millimeters of water) rises to 300 millimeters and gradually subsides to 200 millimeters of water.

the production of acute pancreatitis the answer should be to cut the sphincter of Oddi or otherwise to destroy its function. However a number of factors have so far prevented the general acceptance of this procedure. Among these considerations may be mentioned the danger of opening the duodenum to cut the sphincter, the difficulty of cutting the sphincter with certainty transduodenally, and the fear that cholangitis might be produced by duodenal reflux as a result of its destruction. However the greatest deterrent to the adoption of this operation was the lack of complete conviction

among surgeons themselves to the effect that acute pancreatitis was attributable entirely to biliary reflux.

Aside from a few cases due to trauma, hematogenous infection, or interference with the blood supply to the organ by infarction or embolus, it was felt that acute pancreatitis might be produced by factors other than biliary reflux. Spread of infection from the gall bladder through the lymphatics (12) and intrapancreatic obstruction due to hyperplasia of the pancreatic duct epithelium (26) were also considered as etiological factors. Finally authentic cases were described in which acute pancreatitis was found in the absence of a possible common passageway between the biliary and pancreatic ducts since these opened separately into the duodenum (11, 19). However the consensus seemed to indicate that at least 60 per cent of all cases of pancreatitis were due to reflux of bile into the pancreas. Certainly most operative procedures were based on this assumption.

In recent years the conservative treatment of acute pancreatitis has gained almost general advocacy (17, 23, 24). In the great majority of cases this was made possible only by the development of the serum amylase test, by means of which the diagnosis could be made without exploratory laparotomy. The con-

Fig. 2. Effect of 0.1 N normal hydrochloric acid (local application) on the sphincter of Oddi. Local installation of hydrochloric acid causes immediate spasm of the human sphincter of Oddi, the resistance to flow rising from 50 to 300 millimeters of water. The effect lasts for about 10 minutes or until the acid is washed away with water.

Fig. 3 Effect of pain and emotion on the tonus of the sphincter of Oddi. The insertion of a needle into the antecubital vein caused a marked rise in the tonus of the sphincter as a result of fear and pain. When the patient was reminded of the neglect of her only daughter she began to cry, and the tonus of the sphincter increased as the result of a feeling of hostility and resentment. When she was assured that her daughter had telephoned and would come to see her the sphincter could be seen to relax.

servative treatment led to a marked lowering of the mortality rate for acute pancreatitis. However, many of the patients who were thus treated and saved an operation returned for treatment because of recurrent attacks of acute pancreatitis, each attack carrying with it the possibility of either severe complications or a lethal outcome.

Two groups could be distinguished: (1) those with a normal biliary tract described in a classic paper by Comfort and his associates, and (2) those who had previous operations: removal of gall stones, cholecystostomy, or choledochostomy with drainage of the biliary tract for prolonged periods, cholecystectomy, or cholecystogastrostomy. It is these patients, several of whom will be described, who force us to consider the need for developing a definitive surgical procedure for their treatment.

CASE REPORTS

CASE 1. H. W. No. 58318-46, a 36 year old colored male with a 1 year history of recurrent attacks of severe epigastric pain accompanied by nausea and vomiting, was admitted to the Third (N. Y. U.) Surgical Division of Bellevue Hospital on December 2, 1946. Various diagnoses such as gastritis or duodenal ulcer had been made by different physicians. For the past 2 months he had been on a peptic ulcer regimen and had stopped drinking a habit to which he had been excessively addicted. However, on November 28, 1946, he had indulged in a large

Thanksgiving dinner including a number of alcoholic drinks and subsequently developed moderate epigastric pain which lasted until December 2, 1946. On this day he suffered a sudden onset of severe prostrating epigastric pain which radiated to the left shoulder and left groin. On admission to the hospital 8 hours later he was found to have generalized superficial abdominal tenderness with marked tenderness in the epigastrium on deep palpation. Temperature was 100 degrees, white blood count 13,400. A flat plate of the abdomen failed to reveal any free air in the subphrenic regions. The serum amylase carried out the day after admission was 260 milligrams per cent, and a diagnosis of acute pancreatitis was made. The amylase fell to 180 milligrams per cent the following day and to 161 milligrams per cent on the 4th day of the attack. By then his symptoms had disappeared and he was prepared for cholecystographic studies. That night he had a recurrence of pain and the following morning his serum amylase had risen to 302 milligrams per cent. Nevertheless he was given a routine fat meal after a preliminary x-ray examination and 2 hours later his serum amylase had risen to 387 milligrams per cent (Fig. 8). The cholecystogram revealed a normally functioning gall bladder. X-ray examination of his stomach and duodenum failed to reveal any abnormality. He signed out against advice on December 17, 1946 before further studies could be done.

CASE 2. O. T. No. 12709-47, a 44 year old white man was admitted to Bellevue Hospital on March 10, 1946, with complaints of severe epigastric and right upper quadrant pain, abdominal distention and vomiting. He gave a 12 year history of chronic alcoholism and an 18 month history of recurrent attacks of epigastric pain associated with bouts of acute alcoholism. He had been treated at a number

Figs. 4 and 5. Visualization of the pancreatic duct as a result of increased tone of the sphincter of Oddi. Incident spasm (Fig. 4) results in passage of injected iodized oil into the main pancreatic duct (on arrow) and thence into the accessory pancreatic duct of Santorini (two arrows). Pain produced by sudden distention of the common bile duct results in reflex spasm of the sphincter of Oddi and allows injected diodrast (33%) to pass up the pancreatic duct, completely outlining it to the tail (arrow).

Fig. 6

Fig. 7

Figs. 6 and 7. Visualization of the pancreatic duct as a result of spasm of the sphincter of Oddi produced by morphine. Following the administration of $\frac{3}{4}$ grain of morphine previously, the sphincter of Oddi became sufficiently spastic to enable the iodized oil to fill the whole pancreatic duct (arrow). In a patient whose gall bladder had been removed weeks previously, and the cystic duct drained. On slight rotation of the patient (Fig. 7) the junction of the ducts was clearly visualized.

of different hospitals where various diagnoses such as gastritis, cirrhosis of the liver, duodenal ulcer and delirium tremens were made. This last attack began suddenly 33 hours before admission following a meal

eaten after a bout of alcoholism and starvation lasting for 5 days. On admission he appeared acutely ill. His temperature was 98 degrees, white blood count 16,400. There was considerable abdominal disten-

Fig. 8.

Fig. 9.

Figs. 8 and 9. The serum amylase test as an index of the progress of acute pancreatitis. In Case (Fig. 8) the serum amylase dropped to 61 milligrams per cent on the 4th day but following a fat meal there was a recurrence of symptoms and the serum amylase confirmed the recurrence of acute pancreatitis. In Case 2 (Fig. 9) the serum amylase indicated the gradual recovery from the disease.

tion and marked tenderness on deep palpation in the epigastrium and right upper quadrant. X-ray examination of the abdomen failed to reveal free air under the diaphragm. A serum amylase of 400 milligrams per cent established the diagnosis of acute pancreatitis. Under Miller Abbott tube suction and intravenous hydration and nutrition he improved rapidly, and his serum amylase although it rose on the 2nd day of admission gradually subsided (Fig. 9). He developed delirium tremens on the 3rd hospital day and was transferred to the psychiatric division. He improved under appropriate treatment. A cholecystogram showed an apparently normal gall bladder with rather poor concentrating power. X-ray films of the stomach and duodenum failed to reveal any abnormality. He signed out against a vice on April 1, 1947.

These 2 patients might conceivably do well on a regimen of frequent small meals and total abstinence from alcohol. However the danger of recurrent attacks one of which might be lethal would always be present. An operative procedure which would prevent biliary reflux if such an anatomical condition were present should be considered.

The following case illustrates many of the serious complications of recurrent acute pancreatitis one of which nearly led to death.

CASE 3. F. J. No. 51642-46, a 34 year old white male was admitted to Bellevue Hospital for the first time on October 30, 1946 with a 10 year history of recurrent attacks of severe epigastric and left upper quadrant pain associated with chills and fever. The attacks would last from 1 to 4 days occur frequently at irregular intervals although there were periods of 1 to 2 years when he was completely asymptomatic. On 2 occasions the attacks were so severe

that he was hospitalized. During a prolonged severe attack in 1944 the abdomen was explored and an acutely inflamed pancreas with the stomach duodenum and transverse colon adherent to it, was found. Cholecystostomy was performed and biliary drainage was carried out for 6 weeks. Up to the time of this last admission he had never felt quite well suffering from a dull aching epigastric pain and recurrent attacks of acute pain, chills and fever for which he received antimalarial treatment on several occasions in army hospitals. While under observation at Bellevue Hospital he developed a bilateral subphrenic abscess apparently due to rupture of an infected pancreatic cyst. These subphrenic abscesses were drained. Following recovery after an extremely stormy course the following observations were noted: (1) calcification of the head and tail of the pancreas (Fig. 10) (2) a large and swollen pancreas as evidenced by an increase in the duodenal curve (Fig. 11) and by anterior displacement of the stomach (Fig. 12) (3) secretin test on two occasions revealed that the secretion of pancreatic juice was diminished over one half and that the concentration of amylase was one third of normal (4) a diabetic type of glucose tolerance curve 5 months after his last severe attack (Fig. 13). Since his discharge he has had several moderate attacks of pain, has felt weak and has failed to gain weight.

This patient demonstrates all the serious complications of acute recurrent pancreatitis. The prognosis is extremely poor. At best it will mean recurrent attacks of pain increasing inability to digest his food and an increasing tendency to develop a more severe grade of diabetes. However he may develop a recurrence of a pancreatic cyst or even a fatal pancreatitis. It would seem that if a reflux mechanism could be proved in this case destruction

Fig. 5

Figs. 4 and 5. Visualization of the pancreatic duct as a result of increased tone of the sphincter of Oddi. Incidental spasm (Fig. 4) results in passage of injected iodized oil into the main pancreatic duct (on arrow) and thence into the accessory pancreatic duct of Santorini (two arrows). Pain produced by sudden distention of the common bile duct results in reflex spasm of the sphincter of Oddi and allows injected diodrast (35%) to pass up the pancreatic duct, completely outlining it (the tail) (arrow).

Fig. 6

Fig. 7

Figs. 6 and 7. Visualization of the pancreatic duct as a result of spasm of the sphincter of Oddi produced by morphine. Following the administration of $\frac{1}{4}$ grain of morphine, previously the sphincter of Oddi became sufficiently spastic to enable the iodized oil to fill the whole pancreatic duct (arrow). Patient whose gall bladder had been removed weeks previously and the cystic duct drained. On slight rotation of the patient (Fig. 7) the junction of the ducts was clearly visualized.

In different hospitals where various diagnoses such as gastritis, cirrhosis of the liver, duodenal ulcer and delirium tremens were made. This last attack began suddenly 33 hours before admission following a meal

given after a bout of alcoholism and starvation lasting for 5 days. On admission he appeared acutely ill. His temperature was 98 degrees, white blood count 16,400. There was considerable abdominal disten-

Fig. 8.

Fig. 9.

Figs. 8 and 9. The serum amylase test as an index of the progress of acute pancreatitis. In Case (Fig. 8) the serum amylase dropped to 61 milligrams per cent on the 4th day but following a fat meal there was a recurrence of symptoms and the serum amylase confirmed the recurrence of acute pancreatitis. In Case 2 (Fig. 9) the serum amylase indicated the gradual recovery from the disease.

tion and marked tenderness on deep palpation in the epigastrium and right upper quadrant. X-ray examination of the abdomen failed to reveal free air under the diaphragm. A serum amylase of 400 milligrams per cent established the diagnosis of acute pancreatitis. Under Miller Abbott tube suction and intravenous hydration and nutrition he improved rapidly, and his serum amylase although it rose on the day of admission gradually subsided (Fig. 9). He developed delirium tremens on the 3rd hospital day and was transferred to the psychiatric division. He improved under appropriate treatment. A cholecystogram showed an apparently normal gall bladder with rather poor concentrating power. X-ray films of the stomach and duodenum failed to reveal any abnormality. He signed out against a release on April 1, 1947.

These 2 patients might conceivably do well on a regimen of frequent small meals and total abstinence from alcohol. However the danger of recurrent attacks, one of which might be lethal, would always be present. An operative procedure which would prevent biliary reflux if such an anatomical condition were present should be considered.

The following case illustrates many of the serious complications of recurrent acute pancreatitis, one of which nearly led to death.

CASE 3. F. J. No. 51642-46, a 34-year-old white male, was admitted to Bellevue Hospital for the first time on October 30, 1946, with a 10-year history of recurrent attacks of severe epigastric and left upper quadrant pain associated with chills and fever. The attacks would last from 1 to 4 days, occur frequently at irregular intervals, although there were periods of 1 to 2 years when he was completely asymptomatic. On 2 occasions the attacks were so severe

that he was hospitalized. During a prolonged severe attack in 1944, the abdomen was explored and an acutely inflamed pancreas with the stomach, duodenum and transverse colon adherent to it, was found. Cholecystostomy was performed and biliary drainage was carried out for 6 weeks. Up to the time of this last admission he had never felt quite well, suffering from a dull aching epigastric pain and recurrent attacks of acute pain, chills and fever for which he received antimalarial treatment on several occasions in army hospitals. While under observation at Bellevue Hospital he developed a bilateral subphrenic abscess apparently due to rupture of an infected pancreatic cyst. These subphrenic abscesses were drained. Following recovery after an extremely stormy course the following observations were noted: (1) calcification of the head and tail of the pancreas (Fig. 10); (2) a large and swollen pancreas as evidenced by an increase in the duodenal curve (Fig. 11) and by anterior displacement of the stomach (Fig. 12); (3) secretin test on two occasions revealed that the secretion of pancreatic juice was diminished over one half and that the concentration of amylase was one third of normal; (4) a diabetic type of glucose tolerance curve 5 months after his last severe attack (Fig. 13). Since his discharge he has had several moderate attacks of pain, has felt weak, and has failed to gain weight.

This patient demonstrates all the serious complications of acute recurrent pancreatitis. The prognosis is extremely poor. At best it will mean recurrent attacks of pain, increasing inability to digest his food, and an increasing tendency to develop a more severe grade of diabetes. However, he may develop a recurrence of a pancreatic cyst, or even a fatal pancreatitis. It would seem that if a reflux mechanism could be proved in this case, destruction

Fig. 9.

Fig. 10.

Fig. 11.

is clearly shown (arrow). The enlargement of the pancreas is evidenced by increase in the curve of the duodenum (Fig. 10) and by anterior displacement of stomach (Fig. 11).

of his sphincter of Oddi should be considered. However, his condition has progressed so far that a total pancreatectomy may have to be done to cure him.

The next patient illustrates recurrent acute pancreatitis due to obstruction of the papilla of Vater by a stone.

CASE 4. D. C. No. 43136-47, a 37 year old colored woman was admitted for the first time to the 3rd Surgical Division of Bellevue Hospital on September 1, 1946 with a 3 year history of attacks of severe epigastric pain radiating to the back. One month previously she was treated at another hospital for peptic ulcer. The day before admission she devel-

oped a severe attack for which she was admitted to another hospital and then transferred to Bellevue Hospital.

On admission she appeared to be quite ill. Temperature, pulse and white blood cell count were markedly elevated. The abdomen was distended, and tenderness was marked in the epigastrium and right upper quadrant. X-ray films of the abdomen revealed distended small bowel but no fluid levels or free air. A serum amylase taken soon after admission was 256 milligrams per cent. A diagnosis of acute pancreatitis was made, and the patient treated by Miller Abbott tube suction and intravenous hydration. The symptoms subsided rapidly and the serum amylase fell to normal on the fourth day of her illness (Fig. 12). A cholecystogram, done on the ninth day of her illness, failed to visualize the gall bladder. The routine fat meal given with this procedure induced another attack of epigastric pain. Blood amylase taken the next day was 500 milligrams per cent. This high amylase subsided rapidly to normal figures. X-ray examination of the stomach and duodenum was reported normal. A diagnosis of chronic cholecystitis in addition to recurrent acute pancreatitis was made and an exploratory operation was carried out on October 3, 1946. A thin, inflamed cystic duct was dilated and contained 3 stones. The common duct was 2 centimeters in diameter, inflamed and thickened. A number of small stones could be palpated inside it. The head of the pancreas was found somewhat indurated.

After ligating the cystic duct, a needle was introduced into the common duct and lipiodol was injected. A cholangiogram (Fig. 13) revealed the presence of the stones, but the pancreatic duct was not visualized. The gall bladder was removed, and

Fig. 3. The progressive destruction of the pancreas by recurrent attacks of pancreatitis in Case 3 involves not only the acinar cells but the islet cells as well, as shown by the diabetic type of glucose tolerance curve.

Fig. 14. Serum amylase determinations in Case 4 demonstrate the recovery from an attack of acute pancreatitis and the recurrence of the disease following the administration of a fat meal.

the common duct was opened. After removing the calculi a catheter was inserted into the distal part of the duct for a distance of 2 centimeters and secretin administered intravenously. About 4 cubic centimeters of rather mucoid colorless fluid was obtained from the catheter. This proved to be pancreatic juice since on analysis later on it was found to contain 1,000 milligrams per cent of amylase. The common bile duct was drained by a T tube.

Two weeks later, cholangiographic studies revealed a spastic sphincter (Fig. 16). Following the administration of morphine a long narrow rather fixed intramural portion of the bile duct could be visualized (Fig. 17). This did not change after the administration of amyl nitrate. Several cholangiographic studies showed the same picture. The pan-

Fig. 15. Cholangiogram performed on the operating table in a case of acute pancreatitis due to intermittent obstruction of the papilla of Vater by a small stone. The common duct is seen to contain stones, but the pancreatic duct is not visualized due to absence of sufficient obstruction at this time.

creatic duct could not be visualized by the use of morphine. However closure of the T tube produced no symptoms. The tube was removed 40 days after operation. The fistula closed immediately and she has been symptom free since.

We consider this patient one who has a common biliary-pancreatic passageway (reflux mechanism) as proved by the presence of pancreatic juice in the common bile duct after the administration of secretin. The sphincter of Oddi was not sectioned since it was felt at the time of operation that the reflux of bile into the pancreas was due to obstruction by stone and not by spasm. However since the anatomical

Fig. 6.

Fig. 17

Figs. 6 and 17. Acute pancreatitis due to obstruction of the papilla of Vater by a stone (Case 4). Two weeks after removal of the common duct stones, cholangiographic studies show that the sphincter has a normal tone (Fig. 16). Following the administration of morphine the whole biliary tract is outlined, but the pancreatic duct is not visualized. The intramural portion of the common duct is narrowed by compression of the duodenal wall musculature (arrow).

Fig. 8. Visualization of the pancreatic duct at operation in case of recurrent acute pancreatitis of 20 years duration (Case 5). As a result of spasm of the sphincter of Oddi produced by hydrochloric acid injected through a duodenal tube the iodized oil passed up the pancreatic duct (arrow).

condition (a common passageway) remained intact the prognosis has to be guarded since recurrence remains a possibility.

The next patient presented represents the type of case in which two previous operations on the biliary tract had failed to prevent recurrences of extremely severe attacks of pain.

CASE 5. M. H. No. 10100-47 was a 53 year old woman with a history of a cholecystectomy 20 years previously for attacks of severe epigastric pain. The recurrent attacks persisted and 7 years ago following an attack of severe epigastric pain accompanied by

Fig. 9. The piece of tissue removed by the endobiliary sphincterotomy from the sphincter of Oddi in Case 5 shows connective and muscle tissue, glands of the common bile duct wall, and duodenal mucosa.

jaundice (icteric index 40) an exploratory operation was carried out by an extremely able surgeon. The common bile duct was moderately dilated but contained no stones. A chronic pancreatitis, as evidenced by a hard irregular mass in the head of the pancreas was found. To make certain that no obstruction existed a probe was passed down the choledochus into the duodenum which was opened to confirm the passage of the probe. Common duct drainage was maintained for 2 weeks. Attacks recurred 1 year later and steadily grew worse both in severity and frequency in the last 6 months occurring every 2 weeks. She was admitted to 3rd Surgical Division of Bellevue Hospital on February 11, 1947 3 days after the onset of an attack of severe epigastric and left upper quadrant pain associated with nausea vomiting and fever. Her temperature was 102.4 degrees, pulse 110, white blood count 10,000. The abdomen was distended. X-ray examination revealed no free air beneath the diaphragm but showed distended small bowel with fluid

Fig. 20.

Fig.

Figs. 20 and 8. Cholangiographic studies in Case 5, 1 week after sphincterotomy show the free entrance of iodized oil into the duodenum (Fig. 20). Following application of acid to the duodenum (Fig. 8) the pancreatic duct is not visualized. Under similar conditions prior to sphincterotomy the pancreatic duct was visualized (Fig. 8).

levels. Miller Abbott tube suction and intravenous hydration were instituted. The next day the temperature rose to 105.4 degrees but subsided rapidly under treatment. The serum amylase on the fourth, fifth and sixth days of the attack was 22, 40 and 60 milligrams per cent respectively. Following a fat meal on the sixth day it rose to 72 milligrams per cent. On March 4, 1947 the symptoms recurred for 1 day with a rise of temperature to 102 degrees. The serum amylase was 84 milligrams per cent and the blood sugar 201 milligrams per cent. A secretin test on March 20, 1947 revealed a normal response of pancreatic secretion in regard to volume but a very high concentration of amylase. The serum amylase rose from 84 milligrams per cent at the beginning of the test to 160 milligrams per cent at the end of the test. A glucose tolerance curve was normal. X-ray examination of the stomach and duodenum was reported to be normal. On the basis of the past history and findings and by a process of exclusion it was felt that this patient was suffering from attacks of recurrent acute pancreatitis in spite of the fact that a high serum amylase was not detected during the period of observation. The extremely low amylase figures found after the first attack also suggested the recovery phase of pancreatitis as noted by McCorkle and Goldman.

It was felt that the severity of the patient's symptoms justified section of the sphincter of Oddi if it could be shown that a common passageway existed between the bile and pancreatic ducts. Operation was performed on March 24, 1947. The pancreas was found uniformly enlarged and indurated. The common bile duct was exposed and found moderately dilated. The remnant of the cystic duct about 2 centimeters long left behind at the cholecystectomy performed 20 years previously was opened and

Fig. 22. The administration of morphine in Case 5 two weeks after sphincterotomy shows compression of the intramural portion of the common bile duct due to increased tonus of the duodenal wall. This acts as a one-way valve and prevents duodenal reflux after the sphincter of Oddi is cut.

a catheter tied into it. Lipiodol was injected slowly into the biliary tract simultaneously 5 cubic centimeters of 10% normal hydrochloric acid was injected into the duodenum by means of a duodenal tube passed preoperatively. This was done to produce spasm of the sphincter of Oddi without producing contraction of the duodenal musculature in order to set up the optimum conditions for visualization of the pancreatic duct (15). A cholangiogram obtained under these conditions clearly showed the pancreatic duct and proved the presence of reflux (Fig. 18). Accordingly the sphincterotomy to be described later was passed into the duodenum

Fig. 23. Kymographic tracing A of the resistance to flow of bile into the duodenum in Case 5 indicates that the sphincter of Oddi is destroyed functionally since there is no response either to local application of acid or to emotional stimuli. The response to morphine is limited to its action on the duodenal musculature. This tracing can be compared to the response of the intact sphincter to acid and morphine (B superimposed).

pancreas implanted into the jejunum should prevent both diabetes and steatorrhea.

Archibald first suggested sphincterotomy for pancreatitis in 1913 (1) and first performed it transduodenally in 1918 on a patient suffering from recurrent attacks of acute pancreatitis. In all he operated on 8 patients. He was able to follow 6 of these patients and found them symptom free without evidence of cholangitis (3). The objections to performing this operation transduodenally were due to the danger of opening of the duodenum, the difficulty of finding the papilla of Vater with out opening the bile duct and passing a probe down into the duodenum and most important of all the difficulty of cutting of the sphincter transduodenally without destroying the musculature of the duodenum through which the common bile ducts courses obliquely. It is this oblique course through the duodenal wall as Coffey had shown in devising his operation for ureterocolic anastomosis which prevents duodenal reflux. Every time the duodenum contracts both the bile and pancreatic ducts are closed off by the valve like action of the duodenal musculature (Figs. 24 and 25). At Archibald's suggestion an effort was made to develop an instrument which would section the sphincter of Oddi safely through an open

Fig. 26 Endocholechochal sphincterotomy. The length and curvature of the instrument are adapted to insertion into the duodenum through the common duct. Since the handle and knife are in the same side and plane only the anterior free lip of the papilla of Vater can be cut. The length of the effective section is 1 centimeter.

ing in the common bile duct and not through the duodenum and at the same time would not cut the duodenal musculature. Such an instrument was finally perfected by Colp and Doubilet (9) (Figs. 26, 27, 28) and was used successfully in the treatment of dyskinesia of the sphincter of Oddi (4, 5, 7, 8). This instrument was also used by Colp (6) in 1945 in an

Fig. 27

Fig. 28.

Figs. 27 and 28. Endocholechochal sphincterotomy. The instrument is inserted through the common duct into the duodenum until it elevates the anterior duodenal wall (Fig. 27). The blade is then opened to convert the instrument into a book and the instrument withdrawn until it catches the papilla. On closure, the sphincter of Oddi is sectioned in one plane.

attempt to prevent reflux in a patient who developed an acute perforation of the common bile duct as a result of retrojection of the pancreatic juice into the bile duct. Subsequent x ray and kymographic studies failed to show evidence of division of the sphincter.

The curve of the instrument with relation to the anatomy of the bile duct, duodenum and the papilla of Vater is constructed so that it can be used without danger. It will destroy the function of the sphincter of Oddi without interfering with the intramural portion of the common bile duct and so accomplishes the purpose of the operation without danger of a resultant cholangitis.

The cholangiographic and kymographic studies presented here not only corroborate each other but also indicate that the resistance to flow of bile into the duodenum is made up of two components: (1) the sphincter of Oddi and (2) the duodenal musculature. The resistance of the sphincter of Oddi under normal conditions is probably a constant factor. This resistance may be modified by the presence of acid in the duodenum or by the emotional reactions of the individual. On the other hand the resistance produced by the duodenum is equivalent to about 100 to 120 millimeters of water and is increased only during a phase of the passage of a peristaltic wave or by a general increase in intestinal tonus.

Fundamentally the function of the sphincter of Oddi is to increase the resistance to the flow of bile into the duodenum to an extent just sufficient to fill the gall bladder. In animals, destruction of the sphincter leads to complete loss of function of the gall bladder. (9) It ceases to fill and therefore to empty and becomes a collapsed flaccid diverticulum. On physiological principles, the indications are clear that when the sphincter of Oddi is destroyed the gall bladder should be removed. This point should be considered in any future work on the sphincter of Oddi.

The first 2 cases presented are typical of recurrent acute pancreatitis in patients in whom the biliary tract is normal. They pose the problem as to the treatment which would be required to prevent recurrences. The third case represents the serious complications short of death that may ensue as a result of

neglecting to treat these patients with recurrent acute pancreatitis. The fourth case represents the type in which the biliary tract is involved. Merely removing the gall bladder and the common duct stones is not the optimum treatment since the basic anatomical condition, a common passageway between biliary and pancreatic ducts, has not been changed. Case 5 shows definitive treatment of recurrent acute pancreatitis if disease is due to biliary reflux.

CONCLUSIONS

1. Reflux of bile into the pancreatic duct should be prevented by cutting the sphincter of Oddi.
2. Endocholedochal sphincterotomy can be performed with safety without danger of producing cholangitis by duodenal reflux.
3. Endocholedochal sphincterotomy should be the definitive surgical procedure in the treatment of recurrent acute pancreatitis if reflux of bile into the pancreas through a common biliary pancreatic passageway can be demonstrated.

HYPOSPADIAS WITH ENLARGEMENT OF THE PROSTATIC UTRICLE

FREDERICK S. HOWARD, M.D., San Francisco, California

THE prostatic utricle is of interest because it may serve as an indicator of intersexuality in the male. A number of instances of cystic dilatation of the utricle and of greater degrees of persistence of the muellerian ducts are recorded in the literature.¹ The association of enlargement of the utricle with other genital defects such as hypospadias and incomplete testicular descent has long been known (1, 42). It has been suggested that hypospadias in the male is an intersexual manifestation rather than an isolated fusion defect (13, 15). If this theory is correct, congenital enlargement of the utricle might be expected to occur frequently in hypospadias individuals and the degree of differentiation of the muellerian ducts in the female direction should vary in proportion to the severity of the penile deformity. This paper is based upon a study of 14 unselected males undergoing surgical treatment for hypospadias at the University of California Hospital. In 10 of these an abnormal degree of development of the uterovaginal tract has been found. There is also a close correlation between the degree of differentiation of the structures of muellerian derivation and the severity of the penile and other genital anomalies (Table I).

MATERIAL AND METHODS

The cases were selected as follows: (1) they were hospitalized for surgical treatment of congenital hypospadias; (2) testes were demonstrated either by palpation or by laparotomy and biopsy; and (3) permission for cystoscopy was obtainable. The ages of the subjects varied from 1 to 29 years. Minor degrees of hypospadias are not represented since they are not treated surgically. Testicular biopsy was performed only twice. In the

others the gonadal sex was based upon the physical examination.

The urethra was examined endoscopically and the utricle explored with a catheter. When the catheter could be passed for a distance of 2 centimeters or more x-ray films were taken before and after injection of a radio-opaque substance. Twice it was possible to pass the endoscope directly into a vagina. There were no untoward reactions. Table II shows the normal length of the utricle according to various authors. For the purposes of this study the dividing line between normal and abnormal size of the utricle was chosen as the base of the prostate for the child and at a distance of 2 centimeters from the utricular orifice for the adolescent and adult. In only one instance (Case 4) was a measurement close to the dividing line obtained.

ABSTRACTS OF CASES

CASE 1. C.F. This boy was examined July 13, 1945 at the age of 11 years. There were no siblings. The penis was of normal size with a false meatus in the glans. The urethral meatus was 2 millimeters proximal to the coronal sulcus and moderate chordee was present. The scrotum, scrotal contents, and prostate were normal. Cystourethroscopy gave normal findings. The utricle admitted a catheter for 5 millimeters.

CASE 2. M.O. This man was examined August 28, 1944 at the age of 29 years. He had one normal brother. The penis was of normal size with the meatus midway between the penoscrotal junction and the coronal sulcus. Moderate chordee was present. The scrotum, scrotal contents and prostate were normal. Endoscopic examination of the bladder and posterior urethra gave normal findings. The utricle admitted a catheter for 5 millimeters. The ejaculatory ducts were easily identified.

CASE 3. H.D. This patient was examined December 12, 1943 at the age of 17 years. He had one normal brother and one normal sister. Hypospadias and imperforate anus were present at birth. Following proctoplasty at the age of 3 days he developed a fistula between the bulbous urethra and the perianal scar. This fistula later was closed surgically. The penis was of normal size with the urethral meatus midway between the penoscrotal junction and

the coronal sulcus. Moderate chordee was present. The scrotum, scrotal contents and prostate were normal. The bladder and posterior urethra were normal endoscopically. The utricle admitted a catheter for 1 centimeter. The ejaculatory ducts were identified.

CASE 4. W. R. This man was examined June 9, 1945 at the age of 33 years. He had one normal brother. The penis was at the lower limits of normal size. The meatus was midway between the penoscrotal junction and the coronal sulcus and moderate chordee was present. The right testicle was normal and fully descended. An atrophic left testicle was palpable outside the external inguinal ring. The prostate was normal. The bladder and posterior urethra were normal endoscopically. The utricle admitted a catheter for 3 centimeters but could not be distended by injection. The ejaculatory ducts were identified.

CASE 5. R. E. This child was examined January 7, 1944 at the age of 2 years. He had one normal

sister. A congenital umbilical hernia was present. The penis was of normal size with the urethral meatus at the penoscrotal junction and moderate chordee. The scrotum, scrotal contents, and prostate were normal. Cystourethroscopy showed a large utricular orifice in the normal position. Dimensions of the utricle as measured on the x-ray films were 2.0 by 0.6 by 0.6 centimeters.

CASE 6. G. C. (Fig. 1) This child was examined April 9, 1945 at the age of 3½ years. He had one normal sister. The penis was normal in size but with the meatus at the penoscrotal junction and moderate chordee. The scrotum, scrotal contents, and prostate were normal. Urethroscopy showed a large utricular orifice surrounded by hymen-like flaps standing in a slight elevation representing the verumontanum. The right ejaculatory duct was identified. X-ray visualization showed a large utricle with several diverticula. The dimensions of the utricle were 4.5 by 3.0 by 3.0 centimeters.

CASE 7. G. A. This boy was examined September 13, 1945 at the age of 14 years. He had one normal brother and one normal sister. The penis was normal in size but with the urethral meatus in the anterior portion of a partially cleft scrotum. Marked chordee was present. The testicles were normal and fully descended. The prostate was normal. Urethroscopy showed a mushroom-shaped verumontanum with a large utricular orifice. The ejaculatory ducts were not identified. The utricle measured 5.0 by 1.6 by 1.5 centimeters.

CASE 8. E. R. (Fig. 2) This young man was examined August 28, 1944 at the age of 21 years. There were no siblings. The penis was slightly smaller than normal. The meatus was in the anterior portion of a partially cleft scrotum. Marked chordee

was present. The testicles were slightly smaller and softer than normal. The left testicle was fully descended but the right was in the upper scrotum. The prostate was normal. Urethroscopy showed replacement of the verumontanum by frond like flaps of mucous membrane overlying the utricular orifice. The utricle measured 6.4 by 2.8 by 3.0 centimeters.

CASE 9. C I. This boy was examined December 13, 1943 at the age of 8 years. There were no siblings. The penis was slightly smaller than normal with the meatus at the penoscrotal juncture and marked chordee. The scrotum was partially cleft. The right testicle was normal and fully descended. The left testicle lay just outside the external ring at this time but descended spontaneously 3 years later. The prostate was normal. The dimensions of the utricle were 3.3 by 1.6 by 1.4 centimeters.

CASE 10. D U. This boy was examined May 11, 1945 at the age of 6 years. He was born after 7½ months gestation. There were no siblings. The penis was slightly smaller than normal with the meatus at the penoscrotal juncture and marked chordee. The testicles were felt just outside the external inguinal rings, but could be brought easily into the partially cleft scrotum. The prostate was normal. The utricle measured 2.4 by 0.7 by 0.8 centimeters.

CASE 11. J P. (Fig 3). This patient was examined November 11, 1943 at the age of 14 months. There were no siblings. He was born weighing 1200 grams after 7 months gestation. Growth and development were slow and the bone-age was retarded. The penis was small with the urethral meatus in midscrotum. Marked chordee was present. The scrotum was bifid. The right testicle was palpable at the external ring. The left testicle was not palpable at this time

Fig 1. Case 6. Dilated utricle with diverticula occurring in association with penoscrotal hypospadias.

but became palpable at the external ring at the age of 2½ years. A prostate was palpable and the prostatic urethra was normal endoscopically. The utricle measured 2.5 by 1.0 by 0.9 centimeters.

CASE 12. W S. This college student was examined September 5, 1944 at the age of 22 years. He had 3 normal brothers and 1 normal sister. His mother a brother was said to have a feminine appearance but details were not available. The body con-

Fig 2. Case 8. A large utricle filled by retrograde injection is shown in anteroposterior and oblique projections. This patient also has penoscrotal hypospadias and an incompletely descended right testicle.

Fig. 3. Case 12. These anteroposterior and lateral views show dilated uterine cavity after injection. Perineal hypospadias and bilateral inguinal cryptorchidism are also present.

Fig. 4. Case 13. A catheter passed into the urethra; contrast has traversed the urethra and entered the cervix. In the injection of radio-opaque salt has filled the urethra and the uterus. The contrast substance has entered the vagina through the right uterine cornu, visualized the epididymis,

four was somewhat feminine. The facial hair was downy. The escutcheon was feminine but the penis was not developed. His voice was high pitched. Large breasts with little glandular tissue had begun their development at the age of 12 years. Erections were infrequent and there had never been any discharge of semen. He was psychometrically masculine. The penis was 5 centimeters long. The urethra opened behind a labial scrotum and marked chordee was present. The left testicle, a full 6 centimeters, descended but pubescent in size while the still smaller right testicle was palpable at the external ring. 17 chromosomes were clearly identified. The prostate was 15 to 35 normal size. Urinary 17-ketosteroid estimation gave normal male values. Urinary gonadotropin estimation gave constant values of from 15 to 25 mouse units, a figure well within the range for normal men. The urethra was endoscopically masculine with visible secretion expressible from the prostatic ducts. Ejaculatory ducts were not identified. The uterine measured 2.0 by 2.5 by 1.5 centimeters.

CASE 13. W.I. (Fig. 4). This boy, examined November 5, 1943, at the age of 3 years, had two normal sisters and 2 normal brothers. He appeared small with marked chordee. The urethral meatus was in the perineum. The scrotum, a cleft and also deficient on the left. The right testicle was palpable at the external ring and its identity was proven

by palpation, and extravasated into the tunica vaginalis. The arrow lies over the inguinal testicle. The lower limit of the bladder is outlined by the contrast material. There is no evidence of contrast material entering the bladder region.

Fig. 5. Case 14. Injection through the vaginal orifice in the urogenital sinus has visualized the vagina, uterus, and

uterine tubes. This patient possesses small pelvic testes. There are no ovaries.

by biopsy. The left gonad was absent but a poorly developed left epididymis was found in the pelvis. An infantile bipartite uterus in communication with a vagina entering the posterior urethra just proximal to the external sphincter was demonstrated by x ray examination and by laparotomy. The right vas deferens communicated with the uterus. The left vas was incomplete and blind. Uterine tubes and seminal vesicles were not identified. The posterior urethra felt slightly thickened on rectourethral palpation but a prostate was not certainly identifiable. Laparotomy was performed on this patient for determination of the nature of the left gonad. The vagina, first demonstrable only by x ray examination, was examined directly with the cystoscope 3 years later finding a single external os. Following a urethroplasty and perineal urethrotomy with catheter drainage in 1946 the patient developed a febrile infection caused by accumulation of infected urine and pus in the vagina. This infection was successfully treated by endoscopic lavage.

CASE 14. M.H. (Fig. 5) This young man was examined May 16, 1945 at the age of 20 years. He had 3 normal brothers and 2 normal sisters. He had been brought up as a girl but the bodily contour, breasts and voice were masculine. His facial hair required shaving thrice weekly. He had never menstruated. Psychometric tests gave strongly masculine findings. The penis was markedly incurvated and measured 7 centimeters. Laparotomy disclosed atrophic pelvic testes and epididymides. The nature of the gonads was proved by biopsy. No vasa seminal vesicles or prostate could be found. A small uterus and uterine tubes were present. The vagina entered the urethra distal to the external sphincter forming a short persistent urogenital sinus opening in the perineum. The scrotum was undeveloped and resembled labia majora. No urethral glands or verumontanum were demonstrable endoscopically.

Determination of the 24 hour urinary 17 ketosteroid excretion gave values of 13.6 for the total and 8.8 for the ketonic fraction, figures which are borderline between the average findings for males or females.

Exploratory laparotomy was performed for determination of gonadal sex. Later the patient's legal sex was changed to male and plastic procedures on the penis were performed.

DISCUSSION OF FINDINGS

Anatomically these 14 individuals may be divided into three groups. In group I (Fig. 6) penile hypospadias is the only departure from normal. In group II (Fig. 7) penoscrotal or perineal hypospadias is present with increasing degrees of chordee and diminution of the size of the penis. Anomalies of testicular descent and size are frequent and the prostate may be poorly developed. The normal prostatic utricle is replaced by a rudimentary vagina entering the urethra at the verumontanum which is frequently abnormal and sometimes occupies a position caudal to the normal. A uterus and uterine tubes are not demonstrable. The dilated utricle is normally empty and its thin walls are not noticeable on palpation of the prostate. On urethroscopy the utricular orifice is larger than normal and sometimes surrounded by hymen-like flaps. On catheterization of the orifice and distention of the utricle with fluid a soft pyriform or ovoid mass lying usually a little to the right or left of the midline is easily

felt extending upward from the midportion of the prostate between the genitourinary tract and the rectum (Figs 1 2 3) After withdrawing the catheter the organ readily empties itself spontaneously In group III (Fig 8) the external genitalia closely resemble those of the female. The testicles are incompletely descended The prostate seminal vesicles, and vasa deferentia are poorly developed or absent and a rudimentary uterus is present with the vagina communicating with the posterior urethra or uniting with the urethra distal to the external urinary sphincter to form a persistent urogenital sinus. The uterovaginal tract may be demonstrated by x ray examination (Figs. 4 5) or by direct endoscopy

Except in Case 13 where the vagina became temporarily infected during a period of urethral catheter drainage the 10 patients in this series possessing abnormal muellerian remnants have shown no signs of urinary tract obstruction or infection nor have they complained of pain or other symptoms attributable to these anomalies In no case has surgical removal of the vagina or uterus been considered necessary

These young men and boys appear masculine in behavior and temperament and generally in physique although evidences of mild to moderate hypogonadism are present in Cases 8 11 12 and 14 Of possible etiological significance in a negative sense is the absence of a family history of urogenital anomalies and the relationship of 13 normal brothers and 9 normal sisters to the group as a whole. Extraurogenital anomalies are infrequent.

DISCUSSION OF THE SIGNIFICANCE OF DILATATION OF THE UTRICLE

The association of any other genital anomalies with dilatation of the prostatic utricle is by no means uniform nor is the condition always congenital Several possible causes are to be considered (1) inflammation (2) neoplasia (3) local developmental errors and (4) intersexual development of the embryo

Springer in 600 male autopsies found 3 utricular cysts in adults and one in a child These cysts did not communicate with the urethra Because of the finding of associated inflammation of verumontanum and prostate

he concluded that the cystic dilatation was secondary to inflammatory closure of the utricular orifice Michailow by endoscopy and von Gaza by surgical exposure observed and treated utricular cysts which they felt on clinical grounds were inflammatory R. A. Moore (32) in 678 autopsy specimens found instances of cystic dilatation of the utricle but was unable to determine whether they were congenital or the result of inflammation.

At least 5 cases of massive retrovesical cysts apparently resulting from a benign adenomatous process in the utricle or a nearby muellerian duct rest have been reported (2 8 11 18 36)

Several possible local deviations from normal development are capable of causing utricular enlargement. Englich, on the basis of autopsy studies, suggested that cystic dilatation of the utricle may arise from valve formation or fusion of the fetal mucosa membrane at the point where the muellerian ducts enter the urogenital sinus. Boshamer in a clinical study of 4 adults with utricular cysts within the verumontanum not communicating with the urethra concluded that these cysts arose from a purely local developmental error because of the absence of signs of inflammation and of associated congenital defects In certain mammals particularly in ruminants the utricle is normally a small cyst distinct from the urethra (22 38) Siddiqui has shown in the ground squirrel that the growing muellerian ducts of the male embryo never reach the urogenital sinus. In the adult male of this species the prostatic utricle is either absent or present as a small rounded structure which does not communicate with the urethra. Whether this is the mechanism of development of the normal closed utricle of cattle is not known nor is there proof that analogous incomplete growth of the caudal ends of the muellerian ducts occurs in the human. However an atavistic change of this nature provides a ready explanation for isolated congenital cysts of the utricle Squamous metaplasia of the epithelium of the prostatic urethra and utricle in response to maternal estrogen during the latter months of pregnancy has been shown to occur in the human male fetus. When this epithelium desqua-

mates it frequently chokes the cavity of the utricle causing dilatation (5)

Although inflammation neoplasia isolated developmental errors and physiologic epithelial metaplasia account for many instances of enlargement of the utricle the findings in the subjects of this study are best explained on the basis of a feminization of the male embryo. Male pseudohermaphroditism as seen in Case 14 presents a striking example of feminization. The less obvious utricular enlargement with penoscrotal hypospadias becomes significant as an intersexual phenomenon when its relationship to the associated genital anomalies is considered from the embryologic standpoint.

A corollary to the theory of an intersexual type of development for this kind of utricular anomaly is that hypospadias also has a similar etiology. This view was supported by Felix but Young (46) felt that except in the pseudovaginal type of hypospadias the defect could be explained simply as the result of arrested development. The present study, although based upon a small number of cases has uniformly demonstrated utricular enlargement in penoscrotal and perineal hypospadias. The only difficulty in explaining penile hypospadias on the basis of a simple developmental error is the lack of a satisfactory explanation for the chordee. If feminization of the embryo is assumed to occur this difficulty is overcome, and penile hypospadias may be considered as a minimal degree of intersexual development.

Although Crew was able to correlate the changes in the external genitalia gonads and gonaducts of intersexual goats and pigs according to the degree of deviation from the normal, studies in the human have been lacking. Few cases of enlargement of the utricle in association with hypospadias are reported in the literature (1, 27, 30, 45). This is not surprising since the persistent muellerian structures rarely cause symptoms and routine endoscopic examination is not generally practiced in hypospadias. Actually reference to the presence of a definitive uterus in males with perineal hypospadias is encountered more frequently because the severity of the external deformity leads to surgical exploration (6, 9, 33, 45).

The freemartin of cattle and the congenital adrenogenital syndrome in the human suggest that masculinization of the female fetus by hormonal action sometimes occurs. Whether feminization of a gonadal male fetus takes place on a genetic or an endocrine basis is debatable and cannot be settled here (see Witschi, C. R. Moore and Greene, 15). However, treatment of pregnant rats with estrogen has shown that in this particular form of feminization of the male embryo the changes produced are hypospadias high testes stimulation of the female ducts and inhibition of the male ducts and prostatic changes similar to those observed in the human (16). While there are instances of a well differentiated uterovaginal tract in association with a normal penis and undescended testicles (34, 42) and also instances of large undifferentiated muellerian remnants in men with normal external genitalia (19, 20, 25) a combination of anomalies of both the internal and external genitalia is far more frequently observed.

In the human embryo of 6 weeks, the primordia of the genitalia are present in an asexual form consisting of abdominal gonads the genital tubercle the wolffian ducts and the developing muellerian ducts. In the male embryo of 8 weeks, the gonad is distinguishable as a testis and the wolffian and muellerian ducts have established communication with the urogenital sinus at Mueller's hillock which remains in the adult as the verumontanum. The wolffian system develops rapidly. The mesonephric tubules unite with the tubules of the testis and the mesonephric duct forms primitive seminal vesicles at 10 weeks. During the period between 8 and 10 weeks the muellerian ducts undergo a brief period of incomplete proliferation without ever forming a definitive uterus or oviducts and begin to degenerate at 10 weeks. This degenerative process rapidly goes to completion leaving a remnant of the cranial end of each duct as the appendix testis and a remnant of the fused caudal ends as the prostatic utricle.¹ During

¹Vilas has presented excellent evidence that the epithelium of the human prostatic utricle is all derived from the urogenital sinus contrary to the more generally accepted view that the organ is entirely of muellerian duct origin. In either case, the utricle, at its inception, arises from the growth of the muellerian ducts into the urogenital sinus.

Fig. 6. Group I. Penile hypospadias is the only abnormality present. The testicle, prostate, seminal vesicle and urethra are normal. This constitutes minimal degree of feminization.

the period of from 6 to 10 weeks, the primitive phallus of the male enlarges and the urogenital sinus by a process of folding and fusion of the urethral groove from behind for wards, begins the formation of the urethra which is not complete until the 14th week. During the same period the development of the scrotal swellings the gubernaculum and the formation of the processus vaginalis pre-

Fig. 7. Group II. There is a penoscrotal hypospadias. The testicle is incompletely descended. The penis, prostate, and seminal vesicle are smaller than normal. The urethra is enlarged. Here, feminization is more marked.

pare the field for the descent of the testis. These changes proceed in a co-ordinated manner as the effect of a masculinizing influence upon the undifferentiated primordia. The same primordia under a feminizing influence in the normal gonadal female go through comparable changes in the opposite direction to form the homologous sexual organs. Whether these sex-determining influences are genetic or endocrine in nature is as yet undetermined (15, 31). In the male embryo should a feminizing influence or its equivalent, a deficiency of masculinizing influence occur during the critical period of development it would bring about associated intersexual changes. The extent of these changes is dependent upon the strength and duration of the feminizing influence and the time of the onset of its action. The penis and urethra, going through a longer period of definitive development are most easily disturbed. Factors preparing the way for testicular descent appear to be somewhat less sensitive. The gonads undergo rapid definitive development in an earlier and shorter period. They are altered only by a more profound influence which if sufficiently strong may bring about extreme inhibition of the wolffian ducts and normal female differentiation of the muellerian ducts. Crew interpreting the anatomical gradation of intersexual

Fig. 8. Group III. The penis resembles a large clitoris. The urethral meatus is perineal. An atrophic testis with a rudimentary epididymis lies in contact with the uterine tube in the pelvis. A well developed uterus and vagina are present. The prostate is underdeveloped and seminal vesicles and vasa are absent. Feminization is extreme.

ity in the plg suggested that a minimal masculinizing stimulus is necessary for normal sexual differentiation. Slight deficiency in this influence in time or degree brings about minor abnormalities affecting the external genitalia only greater deficiency produces more marked alteration of the external genitalia plus incomplete müllerian duct recession still greater deficiency causes pseudohermaphroditic abnormalities of the external genitalia differentiation of the uterovaginal tract and incomplete wolffian duct development. Similar gradations of feminization have been produced experimentally in newborn rats by estrogen treatment of the mother during pregnancy (16). The human subjects of the present study (Table I) also may be classified into similar groups group I penile hypospadias group II penoscrotal or perineal hypospadias anomalies of testicular descent dilatation of the prostatic utricle group III the same as group II plus differentiation of the uterovaginal tract absence of the seminal vesicles and incomplete development of the vasa deferentia (Figs. 6 7 8).

CLINICAL SIGNIFICANCE OF DILATATION OF THE PROSTATIC UTRICLE

Individuals with abnormally large utricles in free communication with the urethra rarely exhibit signs or symptoms of disease on this basis. These organs normally remain collapsed and when filled artificially with fluid rapidly empty themselves. Occasionally they may become distended and infected spontaneously or cause obstruction (7 27). In the course of the operative treatment for hypospadias serious infection may occur (Middleton Case 13 of this series). Endoscopy and radiographic exploration of the utricle is of little value in the diagnosis of sex. The demonstration of a vagina or a uterus is not proof of gonadal femaleness. Should a well developed uterus be demonstrated ovaries are most likely present but if only a large utricle without evidence of uterus is present or if vasa deferentia are visualized the gonads are probably testes. The site of vaginourethral communication is also a differential point determinable by endoscopy. Entrance of the vagina into the posterior urethra is a less femi-

nine characteristic than communication between the vagina and urethra distal to the external urinary sphincter (21, 33). While endoscopic and radiographic findings may add to other clinical and laboratory evidence and aid in forming an opinion of the gonadal sex they are not in themselves conclusive.

The discovery of utricular enlargement in hypospadias and the implication that these anomalies represent an intersexual type of development indicate the advisability of studying these individuals clinically as a whole organism rather than as the victims of an isolated fusion defect.

SUMMARY AND CONCLUSIONS

1. An unselected group of 14 males with hypospadias has been studied endoscopically and radiographically for remnants of the caudal ends of the müllerian ducts.
2. In penile hypospadias the utricle is normal. In penoscrotal and perineal hypospadias, the utricle is markedly enlarged and may communicate with a well developed uterus.
3. The findings are presented as evidence for an intersexual type of development rather than a purely local developmental error as the cause of these anomalies.
4. Other causes of utricular dilatation or enlargement are discussed.

Reports of cystic dilatation of utericle and persistence of mesonephros ducts

Chart Distribution of cases according to age group and sex.

DIAGNOSIS

The symptoms of pharyngeal diverticulum listed in Table II varied in duration from a few weeks to 40 years the average being 4½ years. Of these only 1 namely noisy deglutition deserves special mention since it is seldom encountered as a symptom of other lesions producing dysphagia. It occurs when the sac contains fluid and air during swallowing. During this act a gurgling sensation is usually palpable at the site of the sac. Pressure on the neck over the sac will sometimes express its contents into the patient's mouth. In other cases physical signs may be altogether lacking.

While the clinical picture of pharyngeal diverticulum is as a rule typical errors in diagnosis do occur. Occasionally we have

Cough	5	Hemoptysis	

had to differentiate between pharyngeal diverticulum cicatricial stenosis and carcinoma of the cervical esophagus. Although this was accomplished by the roentgenograms alone in the majority of cases, it was often found necessary to have the esophagograms make the final conclusive study. Therefore in all lesions of the pharynx and esophagus we recommend both roentgenologic and esophagoscopy studies.

TREATMENT

Preoperative In this series, the average length of time required to prepare patients for the operation was 5 days. During this period therapy is directed toward correction of nutritional deficiencies such as secondary anemia, hypoproteinemia and avitaminosis by diet and parenteral methods. In a few instances tube feeding was necessary and in 9 cases preliminary gastrostomy. The latter has been per-

TABLE III. — CONCOMITANT DISEASES AND COMPLICATIONS IN LAST 100 CASES

Macrobacteremia (Left vocal cord paralysis, dysphagia, septicemia, thyroid abscess and diverticulum, papilloma of larynx, diabetes, severe lesions requiring gastrostomy)	6	Paralysis With recovery 3 to 4 weeks death	4
		Atherosclerosis	
		Pneumonia and death	
		Aortic aneurysm	
		Coronary atherosclerosis and death	

formed only once in the last 137 cases. Concomitant diseases (Table III) require special attention and often prolong the preoperative period.

In order to decrease inflammatory reaction in the sac wall patients are taught to cleanse and empty the sac after each meal by swallowing water compressing the neck at the area of the sac and leaning forward to let it drain out.

Operative. The salient features of the combined one stage procedure are as follows: first cleansing and emptying of the sac through the esophagoscope; second maintenance of the normal anatomic position of pharynx and upper esophagus by keeping the esophagoscope in the esophagus during ligation of the sac neck and translocation of its stump as well as during the entire period of pharyngeal repair. The restoration of normal anatomic alignment, which is assured by this method, favors normal function after healing has occurred. For this operation we have found open drop ether anesthesia to be the most satisfactory.

a. Esophagoscopy technique. It is important to empty the contents of the pouch since it is common to find secretion and often infrequently masses of food. These should be re-

Fig. 1. Roentgenogram of unusually large pulsion pharyngeal diverticulum, showing fundus of sac extending well into the superior mediastinum.

Fig. 2. Skin incision for pharyngeal diverticulectomy.

moved to prevent overflow into the trachea when the pouch is manipulated.

Identification of the diverticulum by the surgeon can be accomplished promptly if the tip of the esophagoscope is introduced into the pouch so that it can be palpated through the incision and the sac transilluminated. After it is clearly identified and partially separated further esophagoscopic assistance is unnecessary until ligation of the neck of the pouch. The esophagoscope is then introduced into the subdiverticular esophagus guided by an olive-tipped bougie passed over a thread swallowed the day prior to operation. This avoids the occurrence of esophageal stenosis which might ensue if too much of the pharyngeal and upper esophageal walls are removed. In addition it also aids the surgeon in removal of the entire pouch.

At the conclusion of operation a feeding tube is inserted through the esophagoscope into the lower esophagus. The esophagoscope is then removed without disturbing the feeding tube the proximal end of which is withdrawn through the nose.

b. Surgical technique. An incision is made along the anterior border of the left sternocleidomastoid muscle from 1 inch above the sternum to the level of the hyoid bone (Fig. 2) passing through the skin, platysma and deep fascia exposing the anterior belly of the omohyoid muscle. The latter may be severed or

It occurs when the sac contains fluid and air during swallowing. During this act a gurgling sensation is usually palpable at the site of the sac. Pressure on the neck over the sac will sometimes express its contents into the patient's mouth. In other cases physical signs may be altogether lacking.

While the clinical picture of pharyngeal diverticulum is as a rule typical, errors in diagnosis do occur. Occasionally we have

had to differentiate between pharyngeal diverticulum, cicatricial stenosis, and carcinoma of the cervical esophagus. Although this was accomplished by the roentgenologic alone in the majority of cases, it was often found necessary to have the esophagoscopist make the final conclusive study. Therefore in all lesions of the pharynx and esophagus we recommend both roentgenologic and esophagoscopic studies.

TREATMENT

Preoperative. In this series the average length of time required to prepare patients for the operation was 5 days. During this period therapy is directed toward correction of nutritional deficiencies such as secondary anemia, hypoproteinemia, and avitaminosis by diet and parenteral methods. In a few instances tube feeding was necessary and in 9 cases preliminary gastrostomy. The latter has been per-

of the transfusion suture are used and the stump is transplanted upward beneath the inferior constrictor muscle (Fig. 4a). The muscular defect in the pharyngeal wall is now corrected by approximating the upper margin of the cricopharyngeus to the lower margin of the inferior constrictor with interrupted No. 1 chromic sutures spaced about 1 centimeter apart (Fig. 4b and c). The posterior portion of the suture line which overlies the retropharyngeal space is anchored to the prevertebral fascia (Fig. 4d, e and f). This important stitch obliterates the retropharyngeal space at this point, erects a barrier against descending infection into the mediastinum by way of the retropharyngeal space, and reinforces the posterior portion of the suture line. The incision is closed in layers around a small Penrose drain placed in the lower pole of the wound. The average operating time for this procedure was 45 minutes.

Postoperative. The usual hospital stay after operation is 21 days, but only during the first 5 to 7 days is the patient confined to bed. The

wound is treated as in any clean case and the Penrose drain is removed on the seventh day. A concentrated liquid diet is administered through the indwelling nasal tube in increasing amounts according to the plan in Table IV. In order to maintain nutritional and fluid

retracted. The diverticulum is then approached by incising the pretracheal fascia near its lateral margin, retracting the contents of the carotid sheath laterally and the thyroid gland and trachea medially. It is sometimes necessary to divide the inferior thyroid vessels for better exposure.

The fundus of the sac, which is now rotated into the wound and transilluminated by the esophagoscopist (Fig. 3a) is grasped with intestinal forceps and drawn upward and outward after which the esophagoscope is withdrawn from the sac. The diverticulum is then entirely freed to its junction point with the pharynx (Fig. 3b). Care must be exercised to free all muscle fibers from its neck, exposing the submucous coat. This will assure stability of the ligature to be placed subsequently by minimizing the amount of tissue included in it.

The neck of even the largest diverticulum is seldom more than $1\frac{1}{2}$ centimeters in diameter. A neck larger than this usually indicates a complete dissection.

A moist sponge is packed in the lower pole of the wound to safeguard the mediastinum from contamination. Then with the esophagoscope in the esophagus a transfixion suture of No. 1 chromic catgut is placed in the sac neck at its junction with the pharynx and the ends left long (Fig. 3c and d). An additional braided silk tie is used for reinforcement when the sac neck is edematous or unusually large. After clamping a hemostat across the sac neck just distal to the ligature, the sac is severed between the ligature and hemostat (Fig. 3e). Phenol and alcohol are applied to the stump (Fig. 3f) following which the protective sponge previously placed is removed. The long ends

OSGOOD-SCHLATTER'S DISEASE

E S R HUGHES M D M S., F.R.C.S (Eng.) Oxford England

A LARGE literature has accumulated on painful tibial tuberosities in the adolescent since attention was directed thereto by Osgood and Schlatter. The disorder is uncommon and save for a few notable exceptions (7, 8) reports have been based on very small series or even on single cases. The development of the tibial tuberosity is complex and an understanding of its normal anatomical features has been obscured by inaccurate descriptions. Moreover indications are rarely present for operative interference. For these reasons it is not surprising that there should be widely varying interpretations of the pathological changes which take place in the presence of Osgood Schlatter's disease.

THE ANATOMY OF THE TIBIAL TUBEROSITY

The tibial tuberosity has a proximal smooth (Fig 1 s) and a distal rough part (Fig 1 r). The proximal surface of the tuberosity is separated from the upper anterior surface of the tibia by a groove (Fig 1 g) that begins at the upper medial corner of the tuberosity, extends to and turns distally along the lateral side of the tubercle as far as the junction of the smooth and rough parts. This groove varies in depth from bone to bone but is constantly present.

The ligamentum patellae is inserted into the groove and into the smooth part. Investigation has proved that this insertion is strongest in the groove and less so in the tibial tuberosity (3). The deep infrapatellar bursa is related to the tibia immediately proximal to the groove (Fig 1 h); this bursal area may be poorly defined but in many cases stands actually to overshadow the tuberosity itself. The line of demarcation between the smooth and rough halves of the tuberosity lies obliquely like the groove extending farther distally on the lateral side. This line of demarcation indicates the

site of fusion which has taken place between the apophysis and diaphysis.

THE DEVELOPMENT OF THE TIBIAL TUBEROSITY

The conclusions in Table I are based on the examination of more than 100 x ray films. Interpretation of roentgenograms depicting such a small area is made difficult by the marked variation in the films resulting from projections at slightly different angles. The observations are in agreement with those of Perrot who conducted a similar investigation. The development of one or more apophyseal centers at the age of 11 years, their fusion with each other and with the epiphyseal tongue a few months later and the closure of the apophyso-epiphyseal line at about 15 years of age are now fairly generally accepted. Development proceeds a little more rapidly in females.

THE RADIOLOGICAL APPEARANCES IN ADOLESCENT PAINFUL TIBIAL TUBEROSITY

Since 1940 17 children seen at this hospital have been found to be suffering from the con-

Apophysis the term is used here to denote part of the epiphysis which ossifies from a separate center or centers.

Fig. Anatomy of tibial tuberosity: s Proximal smooth and r distal rough part; g groove; h bursal area.

From the Wingfield Morris Orthopaedic Hospital.
Dr. Hughes is holder of travelling fellowship of the National Health and Medical Research Council, Australia.

balance during the first few days additional fluids and vitamins are administered parenterally. The nasal tube is left in place for 18 days acting as a splint during the healing process. A day or two after its removal roentgenologic examination of swallowing function is done. By this time the operative site is healed and a soft diet readily tolerated.

COMPLICATIONS

Complications occurring in the early cases of this series have been described in previous reports (1, 2). Those occurring in the last 100 cases are listed in Table III. The most frequently observed complication was unilateral vocal cord paralysis which was temporary in all instances. The normal location of the recurrent nerve at the lower border of the inferior constrictor muscle is a vulnerable one. In 1 instance paralysis of the left vocal cord was present before operation. Injury to this nerve can only be minimized by exercising care during retraction of the thyroid gland and trachea, freeing of the sac and repair of the pharyngeal wall.

Only 1 of the wound infections did not respond readily to chemotherapy and local conservative measures. In this instance a fistula persisted for 10 weeks but then remained healed. Mediastinitis was not encountered in the entire series of 186 cases.

In several instances, postoperative roentgenologic examination revealed retention of a speck of barium at the operative site. These

dimples were not associated with stricture and the patients were considered cured. One patient, however, was well for 6 months, then had a mild recurrence of symptoms. Roentgenologic and esophagoscopy examinations revealed a pharyngeal sac which was deemed too small to warrant reoperation at that time. She was advised to return for follow up 6 months later but failed to do so.

In the entire series of 186 cases there were 5 deaths or a mortality of approximately 3 per cent. The causes were pneumonia in 2 instances, uremia in 1, uremia with parotitis in 1, and coronary occlusion in 1. It is therefore apparent that the mortality of one stage pharyngeal diverticulectomy is no greater than would be expected for any other major operation in this age group.

CONCLUSIONS

1. Combined surgical and esophagoscopic technique for the one stage removal of polypoid pharyngeal diverticulum herein described represents a sound anatomic and physiological approach to the treatment of this lesion.

2. Experience in 186 cases has shown this method to be safe and effective.

Since this paper was submitted for publication 4 additional patients have been operated upon with similar results.

sis of the underlying bone is also shown (Figs 17 to 20) this rarefaction is localized to the surface of the apophysis.

THE PROGNOSIS IN ADOLESCENT PAINFUL TIBIAL TUBEROSITY

A small number of patients were re-examined at intervals varying from 1 to 9 years after the onset. 2 others, aged 26 and 34 respectively, sought advice for persistent recurrence of pain in the region of the tuberosity since adolescence. All these patients possessed a prominent tibial tuberosity (the photo-

graphs of the knees of 2 patients are reproduced in Figs. 22 and 23). The tuberosity in some cases was tender on palpation and about half of the patients experienced pain in this region which was precipitated by exercise by kneeling or even by sitting on a chair. A radiological examination showed an enlargement of the tuberosity at the site of the insertion of the ligamentum patellae frequently a separate ossicle was present within the ligamentum and an irregular buttress of bone tends to form just above the tuberosity posterior to the tendon (Figs. 24 to 32).

dition (3 with bilateral involvement) The feature common in all the x ray films is either ossification within or enlargement of the ligamentum patellae. The ossification may be found at the site of insertion into the tuberosity in the ligament at a higher level or at both these sites. The abnormal bone at the ligamentous insertion may be in the form of a linear ridge (Figs. 2 to 10) a plaque of bone (Figs. 11-16) or mottled and irregular ossification (Figs. 17-20). The ossification situated higher in the ligament may be linear or irregular and may be connected with the bone for matum at the insertion by bridges of bone. In

the one x ray film which showed no ossification within the tendon (Fig. 21) there was demonstrated a kidney shaped opacity at the site of its insertion.

The epiphysis has united with the apophysis to form a continuous beak, indeed this formation is to be expected since it was found in the normal films of this 12 to 14 year age period (Table I and Fig. 33). The epiphyseal part of the beak is never primarily involved in pathological changes the apophysis also usually escapes. It was found that in those cases in which a mottled irregular ossification is displayed at the site of insertion some osteoporosis

TABLE I — THE DEVELOPMENT OF THE TIBIAL TUBEROSITY

Age group—years	Stage of development of tibia
0-6	The ossification of the epiphysis results in the formation of distinct the proximal end of the tibia diaphysis. There is no extension yet to form the epiphyseal part of the tubercle. The diaphyseal or rounded ball of the tuberosity may or may not be represented by a ledge.
6-8	The epiphysis increases slightly in depth in its anterior part. The diaphyseal ledge is more definite throughout it may be concealed by an oblique projection. The apophysis remains unossified.
8-10	A small tongue of ossification appears from the anterior and inferior edge of the epiphysis. In some films there appears to be an extension of ossification from the diaphyseal ledge into the lower part of the epiphysis but this appearance is due to the obliquity of the ledge.
10-12	The tongue of ossification from the epiphysis continues to extend distally. The distal part of the epiphysis ossifies in most cases from one or more centers. This epiphyseal ossification forms the prominent smooth part of the tubercle and joins the epiphyseal tongue. The site of the groove.
12-14	The epiphysis and epiphysis become continuous. The beak so formed varies very considerably in appearance as does its degree of separation from the diaphysis.
14-16	The line of separation between the combined epiphysis and epiphysis and the diaphysis is slowly obliterated. The oblique and vertical processes of this line appear to be the first to fuse, followed by fusion of the beak and diaphyseal ledge.

Fig. 33 The age incidence of 51 patients seen at this hospital, 1930-1946 inclusive and diagnosed as suffering from Osgood-Schlatter's disease. Total 51; females, 23; males, 28.

there is a disorganization of the apophyseal centers or actual avulsion of a fragment of bone. The finding by some authors that the first radiological sign of this disease is a thickening of the ligamentum patellae (1, 2, 7) the almost constant radiographic demonstration of opaque material within the ligament as described here and as seen in x ray films reproduced by others the increase in density of this material in successive x ray films clearly seen in some of our cases as well as in those published by others all favor the view that Osgood-Schlatter's disease is of the same pathology as myositis ossificans which occurs in the muscle and tendinous fibers of brachialis at the elbow.

With the great number of variations possible in the radiological appearances of the normal tuberosity it is most hazardous to diagnose Osgood-Schlatter's disease from such appearances as increased densities osteoporosis partial separation pitting irregularities and similar conditions. The appearance of fragmentation is a normal stage in the apophyseal development. Osgood-Schlatter's disease cannot be compared with osteochondritis of the hip where fragmentation is a radiological sign of disease. The only definite abnormality of the apophysis observed here was the osteoporosis of the surface at the site of insertion of the ligamentum; this was observed clearly in only 5 cases (Figs. 15, 17, 18, 19, 20) and its presence is accounted for by a reactive hyperemia at the site of the injury. A lack of clear definition of the tuberosity which is apparent

this osteoblastic reaction or to metaplasia of fibroblasts. In either case it would appear that the initiating stimulus is injury to the ligament direct or indirect.

This conception of Osgood-Schlatter's disease as a tendinitis ossificans is in full accordance with all the known facts. Children are affected at an age when osteoblastic activity of this area is at a maximum. The slightly earlier incidence in girls corresponds to their earlier development (Fig. 33). Injury may or may not be recalled but this is an age period when such recollection is difficult. Pain at rest and during exercise a tender enlarged tuberosity the characteristic radiological features all receive an adequate explanation.

Trauma was believed by both Osgood and Schlatter to be the cause of the painful tuberosity and this opinion is now regarded as correct. But its mechanism in the production of the condition has not been clearly understood. Some believe that it causes separation of the tongue-like epiphysis from the diaphysis or even fractures the epiphyseal beak. Others believe that the injury interferes with the blood supply and so causes an aseptic necrosis of the apophysis while others again consider that

DISCUSSION

A knowledge of the normal anatomical and radiological features of the tibial tuberosity in the varying stages of its development is indispensable if the true nature of Osgood-Schlatter's disease is to be understood.

The investigation recorded here shows clearly that the clinical features of this affection are almost certainly due to a pathological change primarily within the ligamentum patellae

rather than in the apophysis. The ossification at the site of insertion is readily accounted for by the partial tearing of the ligamentum from the bone. The insertion of this tendon into the smooth portion of the tuberosity is not as firm as it is into the groove (3) and this may well be the cause of the involvement of the former and the sparing of the latter as seen in most of the early x ray films. The ossification higher in the ligament may be due to an extension of

TABLE I — THE DEVELOPMENT OF THE TIBIAL TUBEROSITY

Age group—years	Stage of development of tibia
0-6	The ossification of the epiphysis results in the formation of the proximal end of the tibial diaphysis. There is no extension yet to form the epiphysal part of the tubercle. The diaphysal or roughened half of the tuberosity may or may not be represented by a ledge.
6-9	The epiphysis increases slightly in depth in its anterior part. The diaphysal ledge is more definite though it may be concealed by an oblique projection. The apophysis remains unossified.
9-12	A small tongue of ossification appears from the anterior and inferior edge of the epiphysis. In some films there appears to be an extension of ossification from the diaphysal ledge into the lower part of the apophysis but this appearance is due to the obliquity of the ledge.
12-14	The tongue of ossification from the epiphysis continues to extend distally. The distal part of the epiphysis ossifies in most cases from one or more centers. This epiphysal ossification forms the prominent smooth part of the tubercle and joins the epiphysal tongue at the site of the groove.
14-16	The apophysis and epiphysis become continuous. The beak so formed varies very considerably in appearance as does its degree of separation from the diaphysis.
16-18	The line of separation between the combined epiphysis and apophysis and the diaphysis is slowly obliterated. The oblique and vertical portions of this line appear to be the first to fuse, followed by fusion of the beak and diaphysal ledge.

this osteoblastic reaction or to metaplasia of fibroblasts. In either case it would appear that the initiating stimulus is injury to the ligament direct or indirect.

This conception of Osgood-Schlatter's disease as a tendinitis ossificans is in full accordance with all the known facts. Children are affected at an age when osteoblastic activity of this area is at a maximum. The slightly earlier incidence in girls corresponds to their earlier development (Fig. 33). Injury may or may not be recalled but this is an age period when such recollection is difficult. Pain at rest and during exercise a tender enlarged tuberosity the characteristic radiological features all receive an adequate explanation.

Trauma was believed by both Osgood and Schlatter to be the cause of the painful tuberosity and this opinion is now regarded as correct. But its mechanism in the production of the condition has not been clearly understood. Some believe that it causes separation of the tongue-like epiphysis from the diaphysis or even fractures the epiphysal beak others believe that the injury interferes with the blood supply and so causes an aseptic necrosis of the apophysis while others again consider that

there is a disorganization of the apophysal centers or actual avulsion of a fragment of bone. The finding by some authors that the first radiological sign of this disease is a thickening of the ligamentum patellae (127) the almost constant radiographic demonstration of opaque material within the ligament as described here and as seen in x ray films reproduced by others the increase in density of this material in successive x ray films clearly seen in some of our cases as well as in those published by others all favor the view that Osgood-Schlatter's disease is of the same pathology as myositis ossificans which occurs in the muscle and tendinous fibers of brachialis at the elbow.

With the great number of variations possible in the radiological appearances of the normal tuberosity it is most hazardous to diagnose Osgood-Schlatter's disease from such appearances as increased densities osteoporosis partial separation pitting irregularities and similar conditions. The appearance of fragmentation is a normal stage in the apophysal development. Osgood-Schlatter's disease cannot be compared with osteochondritis of the hip where fragmentation is a radiological sign of disease. The only definite abnormality of the apophysis observed here was the osteoporosis of the surface at the site of insertion of the ligamentum. This was observed clearly in only 5 cases (Figs. 15, 17, 18, 19, 20) and its presence is accounted for by a reactive hyperemia at the site of the injury. A lack of clear definition of the tuberosity which is apparent

in some of the roentgenograms can be attributed to the presence of changes in the overlying soft tissues

It may be concluded that there is the strongest evidence in support of the belief that Osgood Schlatter's disease is primarily an intraligamentous rather than an epiphyseal condition

SUMMARY

1 The normal anatomy of the tibial tuberosity and the insertion of the ligamentum patellae have been reviewed

2 The development of the tuberosity has been traced radiologically

3 From a study of the condition in the knees it is concluded that the essential lesion in Osgood Schlatter's disease is a "tenositis" rather than an epiphysitis.

BARTHOLIN CYST

A Simple Method for its Restoration to Function

JOSHUA WILLIAM DAVIES A.B., M.D. F.A.C.S.

New York New York

THE vulvovaginal gland (Bartholin) is a racemose gland lying beneath the labia minora. It secretes a clear viscid fluid through its ostium which is located superficial to the hymen in the region of 5 and 7 o'clock. The purpose of the secretion is to lubricate the vulva. As with all glands the amount of secretion varies from time to time but generally speaking the amount of secretion is indicative of the interest in mating.

Bartholin's gland may become diseased and be converted into a cystic formation. Should the cyst become secondarily infected an abscess may result. The latter is limited to the gland and its duct. It rarely extends to the adjacent tissues such as an infection by the streptococcus would produce.

Because of the location of the gland in the vulva disease of this structure should not be interpreted as *prima facie* evidence of a venereal infection. The *Micrococcus catarrhals* is frequently the invading organism in the simple cyst and in the purulent involvement the culture is usually sterile and rarely shows the presence of the gonococcus.

The conversion of the small racemose gland and its duct into a large cyst or abscess suggests a mild infective process originating in or near the minute opening of the vulvovaginal gland which through inflammatory changes occludes the opening of the duct (ostium). The rhythmic secretion of the gland blocked by the occlusion of the duct at its ostium distends the duct and converts it into an apparently large thin walled cystic mass. The patient may frequently detect a periodicity in the distention and regression in the size of the cyst such a rhythm suggests that the gland has not been destroyed by pressure necrosis but that the secreting cells are responding to normal physiological processes.

It should be the objective of the gynecologist to conserve the function of the diseased gland because of its importance in the intelligent interpretation of waves of interest monotonous or fatigue which are present in varying degrees during the process of mating. They are revealed to the male by the presence of lubrication or dryness of the vulva and should suggest a continuation of the mating process or a short period of rest which should be followed by another method of approach if the fullest mental and physical reaction is desired for the female.

The use of vaseline as a lubricant following the surgical removal of the diseased gland may prevent trauma due to dryness and friction but it does not encourage emotional interpretation. The sex act unfortunately frequently becomes a habit and the use of vaseline encourages the routine sex act which tends to become tiresome and fatiguing instead of being enjoyable and stimulating.

Sterility due to tubal spasticity frequently requires consultation with a psychiatrist. His treatment is enhanced by a normally functioning gland which tends to prevent tubal spasticity resulting from friction and trauma.

The restoration of the diseased gland to normal without surgical removal requires an intelligent interpretation of the pathological process responsible for the formation of the cyst as well as an accurate anatomical background. Casper Bartholin (1655-1738) of Copenhagen, Denmark, described the gland but it remained inaccurately described until Bern Gallaudet of Columbia University showed that the gland was a homologue of Cowper's gland and that it lay deep to the bulbos cavernosus muscle and the bulb in the deep compartment of the perineum, i.e. on the deep transverse perineal muscle. Being restrained by the superficial and deep layers of the uro-

in some of the roentgenograms can be attributed to the presence of changes in the overlying soft tissues.

It may be concluded that there is the strongest evidence in support of the belief that Osgood Schlatter's disease is primarily an intraligamentous rather than an epiphyseal condition.

SUMMARY

1. The normal anatomy of the tibial tuberosity and the insertion of the ligamentum patellae have been reviewed.

2. The development of the tuberosity has been traced radiologically.

3. From a study of the knees it is concluded that the disease is Osgood Schlatter's rather than an epiphyseal condition.

remaining secretory cells to regenerate and function

Twenty five cases have been treated by incision close to the hymen in the region of the opening of the duct. The cavity of the cyst is then packed with iodoform gauze which is removed and replaced biweekly for approximately 3 weeks. At the end of this time an opening admitting the blunt end of a pencil represents the newly constructed ostium. The packing prevents the small incision from agglutinating and permits epithelization of the new ostium with squamous epithelium. Ample drainage should permit the diseased gland to return to normal and require no further treatment, but occasionally the ostium may contract and necessitate dilatation with a blunt instrument. The restoration to normal is verified by the disappearance of the mass and the presence of a clear viscid secretion in the region of the fossa navicularis.

COMMENTS

Drainage of the diseased duct is readily accomplished by infiltration with a local anesthetic and incision either in the hospital or in the office depending on the type of patient to be treated. To facilitate packing the edges of the incision should be held with clamps so that the collapsed cyst may not retract into the deeper tissues.

Since the treatment is usually performed in the office confinement to bed is not required.

No case in which this method of treatment was carried out has been complicated by postoperative hemorrhage either immediately following the incision or several days later. The author is familiar with several cases of severe postoperative hemorrhage following the surgical removal of the cyst which required transfusion, packing and even resuturing before the bleeding could be controlled.

CONCLUSIONS

The so called cyst or abscess of Bartholin's gland actually consists of a dilatation of the duct of the gland.

The periodical swelling and recession of the cyst suggest occlusion of the ostium with intermittent drainage.

The swelling of the cyst suggests activity of the secreting cells which lie between the layers of the urogenital diaphragm.

The purpose of the incision and packing of the cyst cavity is to permit restoration of function by the construction of a patent ostium.

Fig. 1. An incision has been made into the cyst close to its original ostium. A strip of iodoform gauze fills the cavity of the evacuated cyst.

Fig. 2. Appearance of the new ostium, 3 months after incision. Five replacements of the packing are required to effect the permanent ostium.

genital diaphragm (triangular ligament) it is impossible for the gland to dissect between the resistant layers to enlarge and become cystic. Instead it is the duct of the gland which becomes distended as it traverses the loose connective tissues between the gland *per se* and its ostium. In the superficial perineal pouch the loose tissues are readily distorted and the dilated cystic duct may cause considerable distortion of the bulb, bulbocavernosus muscle and the labia.

Microscopic study verifies the anatomical finding that the cyst is confined to the duct. Normally the epithelial lining of the Bartholin gland is of the columnar variety while that of the duct is transitional epithelium. The latter variety and even squamous epithelium lines the cavity of enucleated cysts. Careful examination of extensively dissected specimens may reveal a small nodule attached to the cyst which nodule is lined with columnar epithelium. It represents the gland proper.

The final picture is one in which the minute gland lying between the resistant layers of the urogenital diaphragm communicates with a

greatly distended duct which distorts the labia and is adherent to the vulva at the site of its occluded ostium.

Careful surgical removal of the cyst usually results in a rupture of the cyst at its ostium which is in the region of 5 or 7 o'clock and at its attachment to the secreting diaphragm. As a rule the gland *per se* is not removed but the scar tissue resulting from the operative procedure may completely occlude the gland and cause its atrophy.

The author was taught to assume that each case more likely than not, was the result of a venereal infection and that complete enucleation was the treatment of choice. After being consulted by several patients whose complaint was dyspareunia following the bilateral enucleation of Bartholin's cysts, he was influenced by the anatomical position, microscopic study and the frequency of negative cultural reports to change his form of treatment from that of complete excision of the cyst to that of ample drainage and the construction of a permanent ostium which would completely drain the diseased duct and permit the

remaining secretory cells to regenerate and function

Twenty five cases have been treated by incision close to the hymen in the region of the opening of the duct. The cavity of the cyst is then packed with iodoform gauze which is removed and replaced biweekly for approximately 3 weeks. At the end of this time an opening admitting the blunt end of a pencil represents the newly constructed ostium. The packing prevents the small incision from agglutinating and permits epithelization of the new ostium with squamous epithelium. Ample drainage should permit the diseased gland to return to normal and require no further treatment but occasionally the ostium may contract and necessitate dilatation with a blunt instrument. The restoration to normal is verified by the disappearance of the mass and the presence of a clear viscid secretion in the region of the fossa navicularis.

COMMENTS

Drainage of the diseased duct is readily accomplished by infiltration with a local anesthetic and incision either in the hospital or in the office depending on the type of patient to be treated. To facilitate packing the edges of the incision should be held with clamps so that the collapsed cyst may not retract into the deeper tissues.

Since the treatment is usually performed in the office confinement to bed is not required.

No case in which this method of treatment was carried out has been complicated by postoperative hemorrhage either immediately following the incision or several days later. The author is familiar with several cases of severe postoperative hemorrhage following the surgical removal of the cyst which required transfusion, packing and even resuturing before the bleeding could be controlled.

CONCLUSIONS

The so called cyst or abscess of Bartholin's gland actually consists of a dilatation of the duct of the gland.

The periodical swelling and recession of the cyst suggest occlusion of the ostium with intermittent drainage.

The swelling of the cyst suggests activity of the secreting cells which lie between the layers of the urogenital diaphragm.

The purpose of the incision and packing of the cyst cavity is to permit restoration of function by the construction of a patent ostium.

RESULTS AND CAUSES OF FAILURE OF RADIATION THERAPY IN CARCINOMA OF THE CERVIX

HENRY S. KAPLAN, M.D., HUGH M. WILSON, M.D. and
ARTHUR H. MORSE, M.D., F.A.C.S. New Haven, Connecticut

THE combined use of roentgen radiation externally and surface radium application internally has long been widely accepted as the method of choice for the treatment of cervical carcinoma. In recent years, however, this technique has been challenged and a number of other methods including a return to radical surgery have been strongly advocated. Thus the subject has again become a matter of controversy which can be settled only by impartial appraisal and analysis of the 5 year survival rates in comparable series of patients treated by each of the available methods. To this end additional data will be essential for present evidence does not yet permit any final conclusions about the optimal form of treatment in cancer of the cervix. These considerations prompted the present report dealing with survival rates, complications and possible causes of failure in a series of patients treated at the New Haven Hospital, a general hospital of 510 beds during the years 1934 to 1941 inclusive.

CLASSIFICATION OF PATIENTS

One hundred fourteen patients with cervical cancer were treated during this period. Of these 88 were ward patients who received primary radiation therapy. In addition there were 12 private patients, 9 others whose primary treatment was given elsewhere and who were admitted with advanced or terminal disease and 4 patients in whom the diagnosis of carcinoma of the cervix was not clearly established by biopsy. In 1 patient a very early lesion was first discovered in the surgical specimen after total hysterectomy. These miscellaneous groups have been omitted from further study and our attention has been centered on the 88 ward patients because a relatively homogeneous and uniform treatment

plan and clinical work up program was adhered to in this group and because their follow up data are most complete.

The ages of the 88 patients in this selected group ranged from 25 to 81 years, with the greatest concentration of cases in the two decades 40 to 49 years and 50 to 59 years. The distribution by decades, and the number of 5 year survivals per decade are presented in Table I. It can be seen that the age of the patient *per se* was not of great prognostic significance. With the exception of patients in the youngest decade these results are in accord with those reported for a larger series by Healy and Frazell.¹ This finding is at variance with the widespread notion that the outlook for very young patients with cervical cancer is particularly unfavorable. Such patients merit just as prompt aggressive and thorough treatment as women over 50 years of age.

TABLE I — AGE AND SURVIVAL DISTRIBUTIONS BY DECADES

Age, years	20-29	30-39	40-49	50-59	60-69	70-79	80 and over
No. patients	3	6	8	5	5	5	1
5 year survivals	—	6	8	4	5	—	—
Survival per cent	66	100	100	80	100	—	—

Bleeding of variable severity was by far the most common presenting symptom. Aching pain in the lower back or pelvis and foul vaginal discharge were also frequent complaints, while weight loss of significant degree was seldom observed initially. Four patients had no symptoms referable to their tumors; these were detected only during routine physical examinations for unrelated complaints. The duration of symptoms prior to diagnosis varied from a few days to a few years, but this factor appeared to have little or no relation to prognosis or to the extent of disease on initial examination. The fact that the survival rate in

From the Departments of Radiology and of Obstetrics and Gynecology, Yale University School of Medicine.

patients with symptoms for over 2 years was just as high as that in patients in whom the diagnosis was made 'earlier' is probably best explained by variations in the growth rates of the tumors and in the ease with which they bleed.

CLINICAL EVALUATION AND METHOD OF TREATMENT

The patients are usually referred from the admitting clinics or from other services where they have been seen. Although the hospital maintains a general tumor clinic staffed by radiologists, pathologists and surgeons it has been found more convenient to send these individuals to a special tumor clinic operated by the Department of Obstetrics and Gynecology in which patients with neoplasms of the female genital tract are examined, prepared for treatment, and subsequently followed. In addition a central tumor registry supported by grants from the Jane Coffin Childs Fund for Medical Research, maintains a crossfile index of all tumor cases and is charged with the responsibility of getting patients back regularly for periodic follow up examinations.

Patients with suspected cervical cancer are examined bimanually in the special clinic and if this examination is confirmatory, are admitted to the hospital as emergency cases. There, a detailed history is taken and a complete physical examination and biopsy of the cervix are performed. When the biopsy is reported positive for carcinoma the patient is subjected routinely to all of the following diagnostic procedures (1) cystoscopy (2) intravenous urography (retrograde also when necessary) (3) sigmoidoscopy and (4) roentgen examination for metastases which includes a posteroanterior chest film anteroposterior and lateral films of the abdomen pelvis and lumbosacral spine and a single lateral view of the skull. When all of this information concerning the patient is available she is seen jointly by the tumor therapy representatives of the Departments of Obstetrics and Gynecology and of Radiology who perform a careful abdominorectovaginal examination to map out the extent of palpable disease and then reach a decision concerning the optimum method of treatment in each particular case.

Cases have been classified according to the League of Nations plan.

Although an attempt is made to individualize treatment attention is also directed to the dangers of excessive empirical variation in technique and a relatively routinized method has been employed wherever possible in order to facilitate subsequent evaluation of results.

In the usual case treatment starts with external roentgen therapy. It is generally agreed that roentgen radiation should precede rather than follow radium application because it reduces infection in the primary tumor, causes its regression, thus facilitating subsequent radium insertion and tends to seal off the parametrial lymphatics, slowing the spread of disease. Following the recommendations of Arneson and Quimby (2) which were based on a study of the physical distribution of external roentgen radiation in the pelvis 6 portals (2 anterior 2 posterior and 2 lateral) have been employed on all patients whose anteroposterior abdominal measurement was 20 centimeters or more. The lateral portals have been omitted on thinner patients. The usual portal size has been 10 by 15 centimeters, with the inferior outer corner shielded off by lead on the anterior and posterior fields to protect the femoral head. The physical factors have been 200 kilovolts pressure, 20 milliamperes 70 centimeters distance $\frac{1}{8}$ millimeter of copper plus 1 millimeter of aluminum added filtration output 22 roentgens per minute. After the first pelvic cycle of 6 daily treatments 2 portals are treated daily each receiving approximately 250 roentgens. Thus in a 3 to 4 week period a total dose of 1500 to 1800 roentgens measured in air, is delivered to each of the 4 to 6 portals.

The patient is seen in the gynecological tumor clinic 2 to 4 weeks after the completion of x ray therapy re-examined and scheduled for hospital admission and radium insertion. Ordinarily repeat biopsies are not done during or after treatment as it is felt that they may interfere with the healing process and possibly break down fibrous barriers around damaged but still viable cancer tissue.

Radium insertion has been performed under general anesthesia about 4 to 6 weeks after the course of roentgen therapy is finished. This

time interval was selected to permit maximal regression of the tumor and subsidence of the radiation reaction with the feeling that radium application would thus be facilitated and late injuries minimized. The question of the optimal interval between external therapy and radium insertion will be treated at greater length in the discussion below.

For the treatment of cervical cancer platinum cells having a total length of 12 millimeters, an active length of 11 millimeters and a wall thickness of 0.2 millimeter and each containing 3.33 milligrams of radium are enclosed in platinum tubes having a wall thickness of 0.3 millimeter, an active length of 12 millimeters and an overall length of 15 millimeters. Each platinum tube holds either 4 or 8 cells. These tubes are then placed individually in hollow brass cylinders 7 millimeters in diameter about 20 millimeters in overall length each having a wall thickness of 2 millimeters (0.5 mm. pt. equivalent). Thus the total metallic filtration is equivalent to 1.0 millimeter of platinum.

For intrauterine application 2 or 3 cylinders are inserted in tandem into a short length of black rubber tubing which is then tied off at both ends. Eight radium cells are usually placed in the inferior cylinder which lies close to the lower end of the uterine canal and only 4 cells in the upper cylinders. Cylinders, containing 4 cells each are also placed in the hollow rubber corks of a conventional colpostat, and where possible in a third rubber cork which is placed inside the circle of the colpostat bridge against the external os of the cervix. This is essentially the Paris technique developed by Regaud and others. After insertion of the radium the vagina is carefully packed with sulfathiazole-impregnated gauze packing care being taken to displace the bladder and rectum as far from the radium sources as possible. An indwelling catheter is left in the bladder.

In those cases in which the extent of the tumor does not interfere with the standard radium application described a total dosage of 6,000 milligram hours has been employed divided equally between the tandem and colpostat. In the years 1934 to 1936 it was customary to insert the tandem first followed

after an interval of 4 or 5 days by the introduction of the colpostat. More recently both applicators have been used simultaneously the total duration of radium exposure is approximately 70 hours.

Seventeen of the 88 patients received no radium therapy because due either to the local extent of disease or to systemic complications it was felt that radium therapy would not add to the palliation effected by external roentgen treatment alone. Conversely 6 early lesions in which the disease was apparently confined to the cervix were treated by radium alone. In a small number of cases in which combined roentgen and radium therapy was planned, either one or the other was not completed, owing to the development of complications, to failure of the patient to return for treatment, or to errors in follow up. Thus a net total of 58 patients received a full course of radium treatment and 52 of these also received roentgen therapy in the usual dosage range.

RESULTS

The results of radiation therapy in the series of 88 primary ward cases are summarized in Table II. The 5 year survival rates, expressed as percentages of the determinate group, are: 69 per cent for Stage I, 47 per cent for Stage II, 4 per cent in Stage III and 0.0 per cent in Stage IV. The net 5 year survival rate for the entire series was 38 per cent.

In 3 instances, patients who had survived 5 years developed recurrences and died of cancer after 6, 7 and 10 years, respectively. One other patient is living with extensive recurrent disease 7 years after treatment. It is generally accepted that about 10 per cent of those with cervical cancer who survive 5 years will subsequently die of the disease. About half of the patients in our group of survivors have now been followed for 8 to 13 years.

Complications. The number of recorded complications in this series was surprisingly small and they appear to be complications of the disease process itself rather than the result of treatment. Two patients had a second primary cancer, one arose in the ovary the other in the breast. These were both far advanced when the cervical cancer was detected and only palliative treatment could be given.

TABLE II—RESULTS OF RADIATION THERAPY IN 83 CASES OF CERVICAL CANCER

	Stage I		Stage II		Stage III		Stage IV		Total	
	Cases	Per cent	Cases	Per cent	Cases	Per cent	Cases	Per cent	Cases	Per cent

One patient who survived 5 years subsequently developed a basal cell carcinoma of the skin of the face which was recently treated.

The presence of vaginal fistulas communicating with either the rectum or bladder at the time of death was recorded in 3 patients. All of these fistulas developed long after radiation therapy in areas of extensive neoplastic involvement and it seems reasonable to conclude that they resulted from the disease rather than from radionecrosis. There were no instances of fistulas or intestinal stricture obstruction or perforation which could be attributed to the radiation therapy employed. These results contrast favorably with the incidence of radiation injuries and fistulas reported elsewhere. Smith found a higher incidence of fistulas in untreated patients than in patients treated with radium and roentgen rays in fractionated or massive doses and concluded that most fistulas can be considered part of the natural course of the disease. That certain methods of treatment are attended by a significantly greater hazard of fistula formation is indicated by the reports of Pitts and Waterman (15), who observed 29 fistulas in 373 patients treated by interstitial radium implantation with or without supplementary roentgen therapy. Recently Meigs (8) advocated a return to the Wertheim operation in the treatment of early cancers of the cervix. Although the mortality in his series of 53 patients was only 1.9 per cent, he noted 5 ureterovaginal fistulas, an incidence of 10.6 per cent. Corcaden Kasabach and Lenz found that the incidence of intestinal radiation in

juries could be brought down from 8.7 per cent to zero by increasing the time and reducing the intensity of treatment. It seems reasonable to conclude that fistulas and other complications may occur as the result of the technique and dosage employed but are not an inevitable sequel to all radiation therapy for cervical cancer.

Metastases Despite the contrary evidence provided by a number of studies in advanced cervical cancer, the clinical impression still persists that remote metastases from carcinoma of the cervix are uncommon. Behney noted distant metastasis in 4.4 per cent of a series of untreated patients and in 21 per cent of treated patients coming to autopsy. Pearson has reviewed the earlier literature on this subject and added his findings in 57 cases of cervical cancer examined postmortem. In this group there were 13 (25 per cent) with remote metastases to the liver, lungs, pleura, peritoneum, kidney, bones or spleen.

In the series reported here 56 patients died of cancer and 13 of these (23.2 per cent) are known to have had distant metastases at autopsy. The actual incidence is undoubtedly higher inasmuch as many patients died at home where postmortem examination was not possible. At the time of treatment 5 of these 13 cases had been classified as Stage I, 1 as Stage II, 4 as Stage III and 3 as Stage IV but all were clinically very extensive by the time death occurred or metastases were noted. Thus remote metastasis is a rather frequent event in carcinoma of the cervix, particularly in relatively advanced cases.

able have interfered with the administration of a full course of treatment in many cases. A review of these instances reveals that 3 patients failed to return for radium therapy at the appointed time and through an oversight, were not sent for through social service channels. These cases were classified as Stage I, II and III respectively, and all 3 failed to survive 5 years. In 4 other Stage I cases, an interval of 2 to 12 months was allowed to elapse between roentgen and radium therapy for similar reasons, but radium was ultimately applied and 3 of these patients are still alive.

Ten patients received incomplete radium therapy as a result of the omission of either the tandem or colpostat. In most instances this was due to difficulty encountered in the insertion of the applicators into a stenotic external os or vaginal vault or to the presence of a stump carcinoma with a short uterine canal. The net result was an inadequate total dose and unsatisfactory distribution of the radiation which should have been corrected in part by an increase in dosage from the other applicators and their reinsertion if necessary after a short interval. These 10 cases were classified in Stages I to III and none of these patients survived 5 years.

Finally a group of 17 patients (9 Stage IV, 6 Stage III, 2 Stage II) received no radium treatment because they were regarded as too far advanced or too old for anything but palliative external radiation. One of the patients with a Stage II lesion was 81 years old at the time of treatment and is still alive and well 11 years later. None of the other 16 patients survived 5 years. In the other patient with a Stage II lesion the coexistence of an extensive inoperable ovarian carcinoma was the reason for withholding radium. While it cannot be doubted that overenthusiastic treatment of patients with Stage IV cancers of the cervix often does more harm than good, it is also true that better palliation can be achieved in some instances by the use of radium as well as external roentgen therapy and the omission of radium in Stage III cases deprives about 1 patient in 4 of a chance for a 5 year survival. Obviously extreme debility or constitutional infirmities may contraindicate the insertion of radium even in patients in whom the local ex-

tent of disease is not great. This situation did not obtain in the majority of patients from whom radium was withheld. In view of our poor results in Stage III and IV cases, the decision to omit radium therapy in almost one half of such patients appears to have been unduly conservative.

We may now consider the possible flaws in our basic plan of using external roentgen therapy followed after an interval of 4 to 6 weeks by the insertion of radium according to the Paris technique. Sandler (16) has clearly indicated the extent to which the width of the upper vagina may influence the radium dosage delivered to various points in the lateral parts of the true pelvis. It is a common observation that stenosis of the upper vagina may follow external roentgen therapy and in a few instances in this series subsequent radium treatment had to be modified or abandoned because of this complication. This stenosis appears to progress rapidly within a few weeks after radiation and a relatively long interval between roentgen and radium therapy therefore tends to increase the frequency with which the condition is encountered when radium insertion is attempted. Secondly after the relatively long interval of 6 weeks almost all of the tissue reaction to preliminary roentgen therapy has disappeared, and a given dose of radium at this time will be relatively less effective than the same dose administered 1 or 2 weeks after the course of roentgen radiation. Thus a relatively long interval has the two-fold effect of decreasing the biological response to a given dose of radium at the same time that it increases the difficulty of applying such a dose.

On the other hand it is to be expected that a shorter interval between x ray and radium treatment will be attended by a greater incidence of radiation injuries as the work of Corraden, Kasabach and Lenz has indicated. A delicate balance must therefore be struck and an interval selected which will afford maximal effectiveness coupled with reasonable safety. In our series the number of complications which could properly be charged to radiation injury was extremely small but this alone does not compensate for the poor survival rates in the relatively advanced cases. Sandler (17) and Tod (23) at the Holt Radium Institute

roentgen dosage to various points in the pelvis is facilitated with these standard applicators. For these reasons a thorough trial of the Manchester technique by American clinics would seem indicated.

Several years ago Merritt advocated the substitution of intravaginal roentgen therapy for radium in the treatment of cervical cancer. Because of difficulty in directing the beam laterally especially in patients with a narrow vaginal vault the distribution of radiation in the pelvis was found to be inferior to that obtained with standard radium techniques (11). Recently however a combined method has been tried at the Memorial Hospital, New York in which the intrauterine radium tandem is still employed and only the vaginal applicators (colpostats, bombs, boxes) are replaced by intravaginal roentgen therapy. Initial reports on this modification as cited above, seem quite favorable (22).

In 1945 Meigs (8) boldly challenged the accepted radiotherapeutic techniques and suggested a return to the radical panhysterectomy of Wertheim. At the time of his report he had performed this operation in 47 elective cases with no deaths and in 6 nonelective cases with 1 death. This low mortality sharply emphasized the advances made by surgery through the introduction of improved operative techniques, more scientific preoperative and postoperative care and the advent of chemotherapy. For years the chief argument against the Wertheim procedure was the high mortality with which it was attended even in the best hands. It is clear that the situation has changed and that the place of surgery in the treatment of cervical carcinoma is in need of re-evaluation. It is not likely however that this method will supplant radiation therapy to any large extent because such low mortality rates can be achieved only by highly experienced surgeons who carefully select their cases. Meigs required his elective cases to be thin, young, in good health and to have an early tumor. The majority of his patients apparently had early Stage I lesions, which are also most susceptible to radiation therapy. One of the prime reasons cited by Meigs for his return to surgery is the frequency with which the pelvic lymph nodes are involved by

occult cancer which he believes, cannot be eradicated by radiotherapy. In his series of 53 patients examination of the lymph nodes in the operative specimen revealed cancer in 8 (17 per cent) but the clinical stage of disease in these cases is not stated. Obviously no final evaluation of the revived Wertheim operation can be made until 5 year survival rates are available for a large series of cases carefully classified by stages. On a *a priori* consideration however it appears that prohibitive mortality rates will limit its use to early cases in which lymph nodes are less often involved and for which suitable radium therapy already offers a very good prognosis.

For many years Taussig (19, 20) advocated iliac lymphadenectomy as a supplementary measure in the treatment of carcinoma of the cervix. Recent improvements in the operative technique have made this a rather simple, safe extraperitoneal procedure which permits the eradication of pelvic lymph nodes almost as effectively as the much more extensive Wertheim operation. The claim by many surgeons that present methods of radiation therapy cannot eradicate cancer in the pelvic lymph nodes is not without foundation. It is generally agreed that metastatic cancer in the submaxillary and cervical nodes cannot be completely destroyed by external radiation alone and that such deposits are best treated by radical neck dissection. The situation in the pelvis is highly analogous to that in the neck, particularly since most of the tumors are epidermoid carcinomas similar to those arising in the mouth. On this basis alone it would seem illogical to expect external radiation (which includes surface radium therapy as well) to accomplish in the pelvic nodes what it cannot do in the neck.

Further support for this point of view is furnished by a comparison of the survival rates and the frequency of lymph node involvement in cancer of the cervix. In Stage I cases 5 year survival rates have ranged between 60 and 100 per cent, with a rough average for the larger series at about 70 per cent. In Stage II a similar estimate would be about 45 per cent, and in Stage III, about 25 per cent. Taylor (21) has reviewed the literature pertaining to the frequency of pelvic lymph node involve-

ment. He found that regional metastases had occurred in about one third of operable cases, and that the incidence of involvement jumped from about 15 per cent in patients in whom the parametria were microscopically free of cancer to 35 to 55 per cent when one or both parametria were directly invaded. If allowance is made for patients dying because of failure to control the primary lesion it is clear that most of the deaths from cervical cancer could be accounted for on the basis of uncontrolled lymph node involvement.

It seems probable therefore that combined roentgen and radium therapy as employed today is incapable of eradicating cancer in the pelvic lymph nodes. More widespread recognition of this fact will undoubtedly result in a renewed trend toward surgery. It would seem that in Stages I, II, and III a combination of radium and roentgen therapy directed at the primary lesion and its direct lateral extensions followed by extraperitoneal lymphadenectomy to clean out possible regional metastases would be a conservative and probably effective step in the right direction.

SUMMARY AND CONCLUSIONS

1. The results in a series of 88 patients with carcinoma of the cervix treated by combined roentgen and radium therapy in a general hospital have been reviewed. The net 5 year survival rate for the whole group was 38 per cent which compares favorably with that reported elsewhere. However when analyzed by stages, almost all of the 5 year survivals were noted to have occurred in the disproportionately large group of operable Stage I and II cases, and the results in more advanced cases are thus shown to have been unsatisfactory.

2. Possible technical modifications which might yield better results are discussed and it

is concluded that the interval between roentgen and radium therapy should be shortened from 6 weeks to 2 weeks or less, that radium dosage should be increased somewhat in advanced cases, that the "Manchester technique" of radium application should be adopted and that extraperitoneal lymphadenectomy should be performed after irradiation in Stages I, II, and III to save patients with regional lymph node involvement.

EXPERIMENTAL STUDY ON LIPOCAIC

JUAN F CANEPA, M D CARLOS A. TANTURI M D., and ROBERTO F BANFI M D.,
Buenos Aires, Argentina

AS a result of experimental studies on fatty infiltration of the liver caused by the removal of the pancreas in dogs Dragstedt and associates (8-11) reported having obtained a fat free alcoholic extract from fresh beef pancreas, with which they claimed to have prevented fatty degeneration of the liver and death of depancreatized dogs that had received insulin and were fed on bread milk and meat.

As choline was not the specific principle of this extract nor was it to be found in the pancreatic juice or in the extracts of other organs with a rich lipid content (brain liver) and in view of the fact that it was found to be active in small doses per os Dragstedt considered it to be a pancreatic hormone different from insulin and indispensable to the normal metabolism of lipids moreover he suggested the name lipocaic for it (11). According to Dragstedt daily doses of 1 to 1.5 grams of the original preparation (equivalent to 100 grams of fresh pancreas) given by mouth prevented or cured a gross lipid surcharge of the liver and other typical symptoms present in depancreatized dogs treated with insulin.

Dragstedt's hormonal theory based on experimental evidence not entirely unassailable was subjected to numerous criticisms. Some of these were successfully answered by him and his co-workers (9-12) but other questions are still open to discussion partly owing to a lack of uniformity among authors not only concerning the methods used for giving rise to fatty infiltration of the liver but also regarding the diets given to animals.

Though the hormonal character of lipocaic is still denied by some experiments carried out on various types of laboratory animals—particularly on dogs and rats—prove that Dragstedt's extract has an unquestionable lipotropic activity which is not due to the pres-

ence of insulin lecithin choline proteins (6, 7, 31) methionine (7) or inositol (25, 30).

Our work was undertaken with the purpose of studying experimentally (a) the metabolic changes occurring in dogs with ligated pancreatic ducts (b) the repercussions which this operation has on the chemical composition of blood, and (c) the preventive and healing effects that the lipotropic principle of the pancreatic extract—prepared after Dragstedt's technique—has on both (a) and (b). Following other authors' footsteps we started by studying the variations of the cholesterol and phospholipid content of the blood of these animals with the object of endeavoring to establish a quantitative relationship between these and the dose of extract administered.

The first observations suggested that the ligation in dogs of the excretory ducts of the pancreas because of the fatty infiltration of the liver it caused (1, 2, 16, 24, 26, 28, 29) necessarily had to produce some changes in the functional activity of this organ. Therefore we carried out further researches on both the prothrombin variations and the blood alkaline phosphatase activity. In some cases we also determined the serum proteins in order to investigate the effect of their decrease on the alterations already observed.

METHODS

The experiments were performed on 10 normal dogs of different sizes in which the pancreatic ducts were ligated according to the technique advocated by Montgomery, Entenman and Chaikoff. A 10 centimeter long mid line incision was made the cut being carried right down to the peritoneum. Once the entire duodenum and pancreas had been delivered and the duct of Wirsung and accessory ducts came into view they were cut between two cotton ligatures. All pancreatic attachments to the duodenum were severed the dissection was carried down to a distance of 2

ment. He found that regional metastases had occurred in about one third of operable cases and that the incidence of involvement jumped from about 15 per cent in patients in whom the parametria were microscopically free of cancer to 35 to 55 per cent when one or both parametria were directly invaded. If allowance is made for patients dying because of failure to control the primary lesion, it is clear that most of the deaths from cervical cancer could be accounted for on the basis of uncontrolled lymph node involvement.

It seems probable therefore that combined roentgen and radium therapy as employed today is incapable of eradicating cancer in the pelvic lymph nodes. More widespread recognition of this fact will undoubtedly result in a renewed trend toward surgery. It would seem that in Stages I, II and III a combination of radium and roentgen therapy directed at the primary lesion and its direct lateral extensions followed by extraperitoneal lymphadenectomy to clean out possible regional metastases would be a conservative and probably effective step in the right direction.

SUMMARY AND CONCLUSIONS

1. The results in a series of 88 patients with carcinoma of the cervix treated by combined roentgen and radium therapy in a general hospital have been reviewed. The net 5 year survival rate for the whole group was 38 per cent which compares favorably with that reported elsewhere. However when analyzed by stages, almost all of the 5 year survivals were noted to have occurred in the disproportionately large group of operable Stage I and II cases, and the results in more advanced cases are thus shown to have been unsatisfactory.

2. Possible technical modifications which might yield better results are discussed and it

is concluded that the interval between roentgen and radium therapy should be shortened from 6 weeks to 2 weeks or less, that radium dosage should be increased somewhat in advanced cases, that the 'Manchester technique' of radium application should be adopted and that extraperitoneal lymphadenectomy should be performed after radiation in Stages I, II and III to save patients with regional lymph node involvement.

Chart 1. Increase in the alkaline phosphatase of serum of the untreated animals (such as in dog 501). Note the difference between the animal treated with lipocaic (dog 661).

For calculating the yield in terms of extract with sugar, it must be taken into account that 60 grams (30 %) of sugar are added to the 200 grams of fluid extract, thus the yield will be 52 per cent.

Bearing in mind these results the following relation may be established: 1 gram of extract with sugar = 0.77 gram of fluid extract = 0.538 gram of dry extract (Dragstedt's lipocaic) therefore one of our capsules containing an average of 0.75 gram of extract with sugar is equivalent to 0.4 gram of dry extract or to 14.3 grams of fresh pancreas.

Characteristics of the extract. The sugarless extract is a thickish substance, of a very light brown color with a strongly salty taste reminiscent of certain cheeses and has a special smell. When completely dry it is a golden colored powder, very hygroscopic, insoluble in ether but easily dissolved in water as well as in hydroalcoholic solutions, diluted acids and saline.

The aqueous solution of the dry extract has no reducing action on Benedict's reagent and its alcohol ketonic extract does not precipitate with diligtonin, either directly or after saponification with potassium hydroxide. There was no demonstrable tryptic activity with Gross's method.

Ashes. By the usual method of calcination the average sample gave 17.3 grams of ashes for every 100 grams of dry extract.

Total nitrogen. In two average samples, the total nitrogen was assayed by Kjeldahl's method. By distillation with Goldberg and Banfi's apparatus (18) the resulting ammonia was collected in a measured volume of sulfuric acid of known normality and then valued by photocolometry with Nessler's reagent.

Results. Sample 1: 11.6 grams of total nitrogen for every 100 grams of dry extract. Sample 2: 10.02 grams of total nitrogen for every 100 grams of dry extract.

Average. 10.31 grams of total nitrogen for every 100 grams of dry extract.

These figures agree with those given by Dragstedt when using his own extract (7). According to him lipocaic prepared by means of his modified technique contains 12.5 grams of methionine and no choline (7).

TESTING THE PANCREATIC EXTRACT

The lipotropic action of the pancreatic extract was tested both as a preventive and corrective agent. This was done by administering it either immediately after ligating the pancreatic ducts (dogs 621, 661 and 681) or at intervals ranging between 38 and 161 days after the operation (dogs 503, 544, 526, 544).

The extract was given by the oral route (capsules) or systemically (subcutaneous injection of the extract dissolved in distilled water or sterile saline solutions).

The different preparations used in our experiments were:

Lipocaic: pancreatic extract prepared by us according to our modification of Dragstedt's method. One capsule contains the equivalent of 14.3 grams of fresh pancreas. For systemic administration an equivalent amount of dry extract was dissolved in 3 milliliters of distilled water or sterile saline.

Preparation. A pancreatic extract prepared as above at a laboratory of medicinal products. We are not familiar with its precise equivalent in terms of fresh pancreas, though we believe it is very close to that of our preparation.

centimeters beyond the lower duct. Only the larger blood vessels were left untouched. Finally pieces of omentum were placed between the pancreas and duodenum and were secured in position by cotton sutures. The abdominal wall was closed in 2 layers, cotton being used in both. Interrupted stitches were used for the fascia and subcuticular sutures for skin.

The dogs were given no food for 48 hours after operation. After this time feeding was started with meat bread milk and sugar. Plenty of water was allowed. This basic ration was used in all experiments. The pancreatic extract for testing was given to the animals in gelatin capsules which were later mixed in the meat. In some cases biopsies of liver tissue were made during the course of the experiment. Necropsy was performed in all animals in order to ascertain the degree of pancreatic atrophy and to remove samples of different organs for pathological study. These specimens were fixed in formalin and embedded in paraffin. The histological sections were colored with hematoxylin-eosin.

Chemical determinations in blood. For the purpose of studying the effect of the ligation of the pancreatic ducts on some of the blood components and the action of lipocain on them the following periodical determinations were carried out: blood sugar (Folin's method), cholesterol in serum (Schoenheimer and Sperry's method), phospholipid in serum (total phospholipids, Subbarow and Fliske's method adapted by Marenzi to a photometer), prothrombin concentration in plasma (Tanturi and Banfi's technique), serum proteins (by pyknometry after Moore and Van Slyke's indications) and alkaline phosphatase in serum (Shinowara, Jones and Reinhart's method). In the latter a modification in the assay of phosphates was introduced and Holman's method was used. In all animals blood was extracted during fasting. Every determination was done within 12 hours of obtaining the samples and only those samples of serum and plasma wholly exempt from hemolysis were used.

PREPARATION OF PANCREATIC EXTRACT WITH LIPOTROPIC ACTIVITY (LIPOCAIC)

Dragstedt's technique with certain modifications was employed for preparing the pancreatic extract (11).

Fresh pancreas from cattle were passed through a mincing machine and the mass was then left to macerate for 24 hours in twice its volume of 95 per cent alcohol, the mixture being shaken at intervals. Once the hydroalcoholic layer had been decanted, the residue was subjected to further extraction with 10 per cent alcohol for a second 24 hours. At the end of this period the extractive fluid was mixed with the former—which had been kept in cold storage—and the residue was macerated twice again. It was proved later that the fourth extraction was useless, so this fourth step has been discontinued.

Finally the residue was squeezed through gauze and all the extractive fluids were mixed and distilled at vacuum at a low temperature (maximum external 43° C. internal 35° C.) in order to recover the alcohol which could be used again in the second and third extractions.

As the alcoholic content of the extractive fluid decreases during the distillation process, the lipids are freed and appear on the surface in the shape of flocculi. These are easily removed by filtration. Thus Dragstedt's costly method of fat-extraction by means of ether is dispensed with. After we devised this method Dragstedt (7) modified his technique, eliminating either process of fat-extraction.

The watery fluid resulting from distillation contains the lipotropic principle. This fluid was filtered and concentrated by vacuum over sulfuric acid and at room temperature until a thickish substance was obtained. This substance was made into a homogeneous paste by adding 30 per cent of its weight of powdered sugar for preservation purposes, and mixing with a spatula. Later gelatin capsules were filled with this paste (approximately 0.75 gram per capsule) and were immediately placed in wide-mouthed glass containers with frosted glass stoppers. These containers were kept in an icebox to prevent the capsules from coming into contact with a humid atmosphere.

The product described is the one we used per se in our experiments. When testing its activity by the systemic route we used the powder obtained by drying the pure extract; no sugar was added and the powder was aseptically dissolved in sterile saline.

We were able to prove the absence of lipids in our preparation by extracting with ether in a Soxhlet apparatus; the powder obtained by total drying of the sugarless extract—the residue thus found, is practically negligible. It was this powder that we extracted with ether which we used in some physical and chemical determinations.

Yield. The yield can be calculated in terms of dry extract, fluid extract or extract with sugar.

Five kilograms of fresh pancreas gives an average of 300 grams of fluid extract, that is, the equivalent to a 4 per cent yield.

As the fluid extract contains 30 per cent of water the 5 kilograms of fresh pancreas are equivalent to 240 grams of dry powder (Dragstedt's lipocain), which means that the yield in dry powder is of 2.4 per cent.

Chart 3. Decrease of total cholesterol and relative increase of free cholesterol in the untreated animals. This is expressed by the free to total cholesterol relation the value of which remains fairly constant under normal conditions (39.8 to 31.5%) and in the dogs treated with lipocaic (dog 661)

59.7 per cent also after 106 days in dog 524 and 109 per cent after 161 days in dog 544

The decrease of phospholipids—sometimes preceded by a slight increase (dogs 501 and 526)—was more or less slow yet constant and always parallel to that of cholesterol (Chart 3). After 51 days the value of this fall was equivalent to the 28 per cent of the initial value in dog 501 after 56 days to 55.3 per cent in dog 503 after 106 days of 48.5 per cent in dog 526 after the same number of days of 55 per cent in dog 524 and after 161 days of 58.4 per cent in dog 544.

The fall of prothrombinemia was an early feature and parallel to the aforesaid blood constituents. In dog 544 this decrease reached the figure of 65.2 per cent of the initial value on the 20th day after operation and in dogs 524 and 526 of 38.7 and 56.8 per cent respectively on the 106th day.

The increase of the alkaline phosphatase activity of serum also appeared early and it rose during the course of time up to figures 22 times higher than the initial value (dog 501)

Preventive action of the pancreatic extract

Different doses of the extract prepared according to our technique were studied in dogs 661 and 581 with the view of studying its capacity for preventing the appearance of the aforementioned blood changes. Capsules were administered to dogs as soon as appetite reappeared viz. on the 2d and 3d days after duct ligation. Daily doses equivalent to 75 grams of fresh pancreas (5 capsules) proved capable of maintaining within normal limits during 3 months the animal's weight, cholesterolemia free to total cholesterol relation and lipidic phosphorus but not prothrombinemia. The latter though never reaching hemorrhagic levels always showed itself irregularly variable.

An interesting feature was observed in the case of phosphatase: it rose during the first days but it began to fall after the 17th day to return to normal on the 58th day. This evolution should be compared to that of untreated dogs in which increase of phosphatase activity is a constant feature (Chart 1)

X preparation. an aqueous solution of a pancreatic extract, for intramuscular injection, manufactured by a firm of medicinal products. According to the makers, each ampul contains 200 milligrams of active substance (5 ml.) and 0.3 per cent of phenol. Its equivalent in terms of fresh pancreas is unknown.

Z preparation. pancreatic autolysate in aqueous solution for intramuscular injection. Also a commercial preparation. Its nitrogen content is not known.

Casein hydrolysate. Prepared after the method of White and Elman (37) by boiling during 6 hours in 2.6 normal sulfuric acid and then precipitating the acid surplus with barium hydroxide. The solution of amino acids, to which 5 per cent glucose was added, was divided and put in sterilized tubes and rendered aseptic by tyndallization. According to Kjeldahl's method 20 milliliters of this solution contain 267 milligrams of total nitrogen. The slow intravenous injection of this preparation caused no intolerance or anaphylaxis in dogs.

RESULTS AND COMMENTS¹

No trouble was ever experienced in feeding or administering the lipocatic capsules in the postoperative stage as the animals always had good appetites. However all of the dogs lost weight during the experimental period. Their stools were of normal appearance at first but after 2 to 3 weeks they became bulky, thickish, of grayish color rich in fats and of offensive smell in some cases associated with gastric and duodenal ulcers blood was detected (dogs 501 and 544). In spite of the loss in weight the animals were always active never having shown signs of apathy or asthenia. Their coats and fur were covered by a greasy secretion.

Under the experimental conditions stated, ligation of the pancreatic ducts in the dog brought about a loss in weight and various organic and metabolic disorders. These results were demonstrated by quantitative changes in the concentration of certain blood constituents and by fatty infiltration of the liver. The blood imbalance became manifest through (a) a drop of serum proteins (b) decrease of the total plasma cholesterol together with a relative rise of free cholesterol (or a fall of ester cholesterol) (c) decrease of the plasma phospholipids (d) drop in plasma prothrombin (e) increase of the alkaline phosphatase activity of serum.

Due to lack of space, the protocols of each individual dog have been omitted.

The loss in weight was notable within a few days after the operation and became more pronounced during the days in which no lipocatic was administered. This weight loss cannot be due to anorexia as the animals were provided with abundant rations and had excellent appetite. It is caused more likely by a disorder of the fat and protein absorptions brought about by the absence of pancreatic enzymes in the intestine. This condition is partly shown by the increase in volume and frequency of stools very rich in fats.

A fall in serum proteins became evident between the 28th and 37th days after the operation (dogs 621, 661 and 681) and can be considered as an indication of absence of the pancreatic proteolytic enzymes in the intestine. As time passed, the hypoproteinemia became more marked, except in those cases in which the casein hydrolysate was injected (dog 671).

A decrease of total cholesterol—sometimes preceded by a slight increase (dogs 501 and 526)—was seen in all cases and became more accentuated in the course of time. It was already apparent on the 17th or 28th day after operation, but the intensity and speed of development of this symptom varied. The decrease value was 58.3 per cent on the 51st day in dog 501, 64.3 per cent on the 56th in dog 503, 65.7 per cent on the 106th day in dog 524, 46.3 per cent also in the 106th day in dog 526 and 68.9 per cent on the 161st day in dog 544.

Parallel to this decrease of total cholesterol there was a relative increase of free cholesterol (Chart 2) this is shown in the relation $\frac{\text{Free cholesterol}}{\text{Total cholesterol}}$ the value of which—according

to our experiments—remains fairly constant under normal conditions (29.8–31.5%).¹

This index underwent more modifications as time passed even when there was a decrease of the total concentrations of total and free cholesterol. The quantitative variations differed according to the animals. After 51 days, it was 62.3 per cent of the initial value in dog 501, 71.5 per cent after 56 days in dog 503, 52.4 per cent after 106 days in dog 526.

¹F/T% means the percentage of free cholesterol. Its reference to total cholesterol.

Chart 3. Decrease of total cholesterol and relative increase of free cholesterol in the untreated animals. This is expressed by the free to total cholesterol relation the value of which remains fairly constant under normal conditions (29.8 to 31.5%) and in the dogs treated with lipocaic (dog 66)

59.7 per cent also after 106 days in dog 524 and 109 per cent after 161 days in dog 544.

The decrease of phospholipids—sometimes preceded by a slight increase (dogs 501 and 526)—was more or less slow yet constant and always parallel to that of cholesterol (Chart 3). According to Kjeldahl's method 30 milliliters of this solution contain 267 milligrams of total nitrogen. The slow intravenous injection of this preparation caused no intolerance or anaphylaxis in dogs.

RESULTS AND COMMENTS¹

No trouble was ever experienced in feeding or administering the lipocae capsules in the postoperative stage as the animals always had good appetites. However all of the dogs lost weight during the experimental period. Their stools were of normal appearance at first but after 2 to 3 weeks they became bulky thickish, of grayish color rich in fats and of offensive smell in some cases associated with gastric and duodenal ulcers, blood was detected (dogs 501 and 544). In spite of the loss in weight the animals were always active never having shown signs of apathy or asthenia. Their coats and fur were covered by a greasy secretion.

Under the experimental conditions stated ligation of the pancreatic ducts in the dog brought about a loss in weight and various organic and metabolic disorders. These results were demonstrated by quantitative changes in the concentration of certain blood constituents and by fatty infiltration of the liver. The blood imbalance became manifest through (a) a drop of serum proteins (b) decrease of the total plasma cholesterol together with a relative rise of free cholesterol (or a fall of ester cholesterol) (c) decrease of the plasma phospholipids (d) drop in plasma prothrombin (e) increase of the alkaline phosphatase activity of serum.

Due to lack of space, the protocols of each individual dog have been omitted.

The loss in weight was notable within a few days after the operation and became more pronounced during the days in which no lipocae was administered. This weight loss cannot be due to anorexia as the animals were provided with abundant rations and had excellent appetite. It is caused more likely by a disorder of the fat and protein absorptions brought about by the absence of pancreatic enzymes in the intestine. This condition is partly shown by the increase in volume and frequency of stools very rich in fats.

A fall in serum proteins became evident between the 28th and 37th days after the operation (dogs 621 661 and 681) and can be considered as an indication of absence of the pancreatic proteolytic enzymes in the intestine. As time passed, the hypoproteinemia became more marked, except in those cases in which the casein hydrolysate was injected (dog 671).

A decrease of total cholesterol—sometimes preceded by a slight increase (dogs 501 and 526)—was seen in all cases and became more accentuated in the course of time. It was already apparent on the 17th or 28th day after operation but the intensity and speed of development of this symptom varied. The decrease value was 58.3 per cent on the 51st day in dog 501 64.3 per cent on the 56th in dog 503 65.7 per cent on the 106th day in dog 524 46.3 per cent also in the 106th day in dog 526 and 68.9 per cent on the 161st day in dog 544.

Parallel to this decrease of total cholesterol there was a relative increase of free cholesterol (Chart 2) this is shown in the relation Free cholesterol the value of which—according to our experiments—remains fairly constant under normal conditions (29.8–31.5%).

This index underwent more modifications as time passed even when there was a decrease of the total concentrations of total and free cholesterol. The quantitative variations differed according to the animals after 51 days it was 62.3 per cent of the initial value in dog 501 71.5 per cent after 56 days in dog 503 52.4 per cent after 106 days in dog 526

FF/T% means the percentage of free cholesterol with reference to total cholesterol.

Chart 4. The increase of the free to total cholesterol relation is prevented or corrected by the administration of lipocaic.

As time passes the response to the oral administration of pancreatic extract becomes both less regular and not so marked (Chart 4). Though there is an improvement in spite of longer treatment the complete recuperation to preoperative levels is never achieved.

Shortage of material prevented us from pursuing these tests for very long periods; however, we suggest the possibility that more prolonged treatment or larger doses may bring about complete corrective action. With reference to the latter, it is worth mentioning that at the end of 8 days the daily administration of 10 capsules of our extract (equivalent to 150 grams of fresh pancreas) failed to exceed the absolute increase of blood cholesterol and lipoidic phosphorus obtained with 5 capsules daily; nevertheless, they improved the free to total cholesterol relation beyond all comparison, notwithstanding the fact that the administration was begun 193 days after duct ligation.

The study of the corrective action of lipocaic on blood hyperphosphatemia (dogs 621

671 and 681) shows that together with cholesterolemia and phospholipemia hyperphosphatemia undergoes a marked decrease with the administration of adequate doses of our preparation.

The corrective action of the γ preparation on the blood changes was tested on dog 524. The administration was started 107 days after operation and although employing doses similar to those of our preparation it proved to be much less active. This striking occurrence with a substance manufactured by the same process as ours was the result we believe of faulty technique. We learned that the temperature to which the extractive fluids was submitted during the concentration process was not controlled, thus the lessened activity due to the thermolabile character of the lipotropic principle of the pancreas (14, 27).

Tests by systemic administration. Injected into dog 526 at the moment when biopsy of liver tissue revealed a large degree of fatty infiltration (Figs 3 and 4) and an abnormal

Chart 3. The decrease of phospholipids also parallels that of cholesterol. The daily administration of 5 capsules of *Lipocae* produces an increase of total cholesterol and phospholipids. The modifications are unquestionably due to the effect of pancreatic extract administration, because figures show that as soon as it is stopped, the blood changes recur moreover they again disappear when treatment is started anew.

A dose of less than 5 capsules was incapable of maintaining a normal blood picture (dog 68x). A subsequent increase to 5 capsules daily restored altered values to normal with the exception of blood proteins and prothrombin phosphatase did not return to its initial value yet decreased to figures close to it.

The administration of 5 capsules daily of the *Y* preparation proved to be more efficient than 3 of our extract daily yet less so than 5 of the latter as shown by the free to total cholesterol relation.

Corrective action of the pancreatic extract. Experiments were also carried out to see whether the extract was capable of correcting the dysfunctions caused by ligation of the pancreatic ducts. This experiment was done by administering the substance 58 112 and 161 days after the operation (dogs 503 562 and 544 respectively) when the values of cholesterol, phosphorus and prothrombin in blood were low and the free to total cholesterol relation increased in the aforesaid proportion.

The daily administration of 5 capsules of our preparation brought about an increase of the total cholesterol phospholipids, and prothrombin together with a decrease of the free to total cholesterol relation. When the administration was started on the 60th day after operation the preoperative levels were exceeded on the 13th day after the treatment was commenced yet if the administration of the extract was begun 113 and 132 days after surgical interference this rise did not take place until after 13 and 20 days, respectively after the administration was started. Prothrombin behavior was irregular dog 524 in which treatment was started latest of all—showed greater increase than that which appeared in dog 526.

The modifications are unquestionably due to the effect of pancreatic extract administration because figures show that as soon as the extract is stopped, the blood changes recur moreover they again disappear when administration of the extract is started anew (Chart 3).

Chart 4. The increase of the free to total cholesterol relation is prevented or corrected by the administration of lipocaic.

As time passes the response to the oral administration of pancreatic extract becomes both less regular and not so marked (Chart 4). Though there is an improvement in spite of longer treatment the complete recuperation to preoperative levels is never achieved.

Shortage of material prevented us from pursuing these tests for very long periods; however we suggest the possibility that more prolonged treatment or larger doses may bring about complete corrective action. With reference to the latter it is worth mentioning that at the end of 8 days the daily administration of 10 capsules of our extract (equivalent to 150 grams of fresh pancreas) failed to exceed the absolute increase of blood cholesterol and lipoidic phosphorus obtained with 5 capsules daily; nevertheless they improved the free to total cholesterol relation beyond all comparison notwithstanding the fact that the administration was begun 193 days after duct ligation.

The study of the corrective action of lipocaic on blood hyperphosphatemia (dogs 621

671 and 681) shows that together with cholesterolemia and phospholipemia, hyperphosphatemia undergoes a marked decrease with the administration of adequate doses of our preparation.

The corrective action of the Y preparation on the blood changes was tested on dog 524. The administration was started 107 days after operation and although employing doses similar to those of our preparation it proved to be much less active. This striking occurrence with a substance manufactured by the same process as ours was the result we believe of faulty technique. We learned that the temperature to which the extractive fluids was submitted during the concentration process was not controlled; thus the lessened activity due to the thermolabile character of the lipotropic principle of the pancreas (14, 27).

Tests by systemic administration. Injected into dog 526 at the moment when biopsy of liver tissue revealed a large degree of fatty infiltration (Figs. 3 and 4) and an abnormal

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

Figs. 1 and 2. Dog 503. Massive fatty infiltration of the liver. The cells of the trabeculae are deformed and round shaped owing to the presence of fat. Now and then a or 3 liver cells of normal appearance can be seen. There is no reaction of the connective framework. Free to total cholesterol relation, over 5 per cent.

Figs. 3 and 4. Dog 526. Liver biopsy performed on the

30th day of experiment and after 67 days without treatment. Marked fatty infiltration in the central trabeculae though less than in dog 503. With more powerful lens, the central cells appear affected by cytoplasmatic contraction; the nuclei remaining unchanged; others had undergone vacuolation and karyolysis (necrobiosis fat pancreas).

blood picture (310th day) our extract brought about a rapid increase of total cholesterol—together with an improved free to total cholesterol relation—and phospholipids but had no effect on prothrombinemia. Taking into account the short treatment (3 days) and the time since the ducts had been ligated the response can well be considered as quantitatively higher than that given by an equivalent dose per os.

The Y preparation tested on dog 524 also proved more active parenterally than by mouth.

We believe that the lesser efficacy of oral administration is due to a partial loss of the lipotropic principle in the intestine caused by both the anomalous absorption and acceler-

ated intestinal transit seen in dogs with ligated pancreatic ducts.

We shall now discuss tests with two other preparations administered systemically which we shall call X and Z.

One milliliter daily of preparation Z given subcutaneously to dog 621 during a fortnight, gave rise to an insignificant increase of total cholesterol together with a higher free to total cholesterol relation and a decrease of phospholipemia; only prothrombin showed a significant improvement.

The daily subcutaneous injection of 4 milliliters of preparation X—started 13 days after oral administration with our extract when cholesterol free to total cholesterol relation and phospholipids in blood had become nor-

Fig. 5

Fig. 5. Dog 544. Liver with perlobular fatty infiltration. The structure of the remaining cells of the lobule is totally unaffected. Free to total cholesterol relation 52 per cent.

Fig. 6. Dog 524. Liver biopsy obtained after 30 days treatment with systemic injection of lipocaic (30th day of experiment).

The hepatic structure is preserved; there is only a slight fatty infiltration of the peripheral cells of the lobules.

Normal connective tissue. Free to total cholesterol relation 37 per cent.

Fig. 7. Dog 524. Appearance of the liver at the end of experiment. The fatty infiltration is somewhat more pronounced than in Figure 6 and always of perlobular localization. Under a more powerful lens, the liver cells are seen with a normal nucleus and cloudy cytoplasm. Slight polymorphonuclear infiltration between the trabeculae. No cell necrosis. Free to total cholesterol relation, 41.5 per cent.

mal—caused these values to drop to abnormal levels at the end of 29 days of treatment with an increase of blood phosphatase and maintenance of hypoproteinememia.

In view of the fact that subsequent administration of our extract corrected the altered values, those results can be attributed to the small activity (or total lack of it) of the preparations X and Z at least in the doses used by us.

Complementary tests. The decrease of serum proteins in all dogs with ligated pancreatic ducts led us to investigate the possible relation between the hypoproteinememia and the other blood changes observed in these animals. Therefore we used daily doses of casein hydrolysate intravenously in amounts equivalent to 267 milligrams of nitrogen. The injection of the hydrolysate alone (dog 621) or as a complement to the oral administration of insufficient doses of our extract (dog 671) or of preparation Y (dog 621) always gave rise to an increase of proteinemia—which in some cases returned to normal—and of protrom-

bin. At the same time there was an adverse effect on the remaining blood components as the cholesterol and lipoidic phosphorus figures dropped while the free to total cholesterol relation and phosphatase activity rose.

Relation between fatty infiltration of the liver and blood changes occurring in dogs with ligated pancreatic ducts. Former papers by Chaikoff, Dragstedt, Rall, and others (4, 10, 12, 16, 17, 29) have shown the intimate relation existing between the fatty infiltration of the liver of dogs without pancreas or with ligated ducts and the variations of cholesterolemia, the cholesterol esters and lipoidic phosphorus to which we add those of blood phosphatase and protrombin.

The following experimental facts prove that our pancreatic extract possesses lipotropic activity:

a. **The absence of fatty infiltration** was noted in the liver of dog 661 (Fig. 8) that received daily doses equivalent to 75 grams of fresh pancreas immediately after having had its pancreatic ducts ligated.

This result cannot be attributed to faulty operative technique as at necropsy complete atrophy of the pancreas was found. Neither can the presence of a few Langerhans islands on the covering omentum be considered as a cause as the same thing was observed in every animal moreover a direct histological control was kept on dog 526 and an indirect one through the absence of diabetes in all animals. Only dog 550 showed a macroscopically identifiable pancreas (although somewhat smaller in size) but in this dog the accessory duct was found patent thus explaining the lack of blood and liver changes.

b The presence of fatty liver (diagnosed macroscopically) in untreated dog 501. The short time which elapsed between ligation of duct and the appearance of this lesion (51 days at the most) shows this case to be an early one, as Chaikoff and associates (24) say that in their experiments the minimum lapse of time was 12 weeks.

Comparing the blood picture of these two opposite experimental conditions (dogs 661 and 501) with that belonging to the dogs subjected to different treatment and studying them with their respective microscopic pictures it is easy to conclude that both the fatty deposit in the liver of dogs with ligated ducts and its mobilization by means of lipocaine can be followed through the variations of total cholesterol free to total cholesterol relation phospholipids and phosphataseemia. However from the quantitative viewpoint this interrelation is so variable in the different animals that we were unable to establish the minimum effective dose of lipocaine.

Free cholesterol and free to total cholesterol relation Dogs with ligated pancreatic ducts show total hypocholesterolemia together with a rise in the relative concentration of free cholesterol (or as some authors describe it a decrease of the cholesterol esters) as shown by an increase of the free to total cholesterol relation. Already described by other investigators (10-29)

We were able to prevent or correct this alteration by the daily administration in doses of 75 grams of our extract of fresh pancreas given both by mouth and systemically

Broadly speaking both indexes have a parallel evolution under the influence of the derivatives of lipotropic treatment, although the quantitative response is inversely related to the time elapsed between the ligation of the ducts and the beginning of treatment. This would seem to suggest that, as time passes, the liver injury caused by the operation, becomes progressively refractory to the lipotropic action of the extract.

However if we compare the histological pictures of our dogs' livers with the free to total cholesterol relation, it seems possible to establish a gross analogy between the value of the latter and the different degrees of fatty infiltration. In fact the progression of the fatty infiltration shown in the photomicrographs is parallel to the increase of the corresponding values of the free to total cholesterol relation, to wit

Fatty infiltration.

Photomicrographs No 1>3=5>7>6

F/T relation % +51>52.5=52.4>41.5>37

Therefore in these dogs a free to total cholesterol relation equal to or higher than 50 per cent can be taken as an index of an intense fatty infiltration of the liver.

The positive response to the lipocaine's lipotropic action has been pointed out as characteristic of fatty livers rich in cholesterol (22). As McHenry suggested such an anti-fatty liver factor may be somehow related—in a manner as yet unknown—with the cholesterol metabolism.

It is also possible that the return to normal of the free to total cholesterol relation may be due to the hepatocyte having regained its capacity to esterize free cholesterol which had been affected during the process of fatty infiltration. Thannhauser and Shaber say that the fall of the cholesterol esters (*Esteremia*) seen in cases of liver injury is caused by an alteration in the liver cell's capacity to esterize free cholesterol with fatty acids. However Gardner and Gainsborough, Bürger and Hahn, and other investigators have challenged the idea of considering the liver as the specific and indispensable center of cholesterol esterification in view of the fact that this function is still present even increased—in hepatomized $\frac{1}{2}$ (30)

Phospholipids As stated before after the pancreatic ducts are ligated there is a fall in the blood content of phospholipids parallel to that of cholesterol however these figures rise and even become normal after lipocaic administration. This fall has also been reported by Chaikoff (4 5 16) in depancreatized dogs treated with insulin or in others with ligated pancreatic ducts it was considered as an index of a decrease of the plasma choline because the latter is found entirely combined as phospholipid (31 32).

According to this author (5) the decrease in circulating choline is not due to its absence in the diet but to a lack of the lipotropic factor of the pancreas which has an enzymatic character and therefore acts through setting free the methionine present in the food proteins. Once absorbed methionine is transformed in to choline i.e. the real lipotropic agent.

The relation existing between choline and methionine has been indisputably proved by du Vigneaud (13 33) in the rat rabbit and man and by McKibbin in the dog. These authors showed that choline arises from methionine thanks to the labile methyls of the latter's molecule. The administration of pancreatic extract—source of Chaikoff's enzymatic factor—would allow the methionine of foods to be used as lipotropic agent with the resulting choline synthesis and increase of plasmatic phospholipids.

Our results although confirming Chaikoff's in the matter of the phospholipemia variations brought about by providing or withdrawing administration of pancreatic extract to dogs with ligated pancreatic ducts do not agree with his theory of the rôle of methionine in this process. This was shown by the fact that the injection of casein hydrolysate had no lipotropic effect as witnessed by the values of cholesterol phospholipids and prothrombin in blood. This statement of ours is made with reservations as we were unable to assay quantitatively the methionine present in the hydrolysate.

Alkaline phosphatase After the pancreatic ducts had been ligated phosphatasemia increased in every animal. Bearing in mind that the rise of alkaline phosphatase activity of blood has been taken as a sensitive index

Fig. 8 Dog 661. No fatty infiltration. Slight granular disintegration of the liver cells with nucleus of normal appearance. Free to total cholesterol relation .33 per cent.

of functional or minimal biliary obstruction (3) it is possible to understand the marked and progressive hyperphosphatasemia in both dogs not having received lipocaic (dog 501) and in those in which the changes in the blood values of cholesterol and phospholipids pointed to the presence of a fatty infiltration of the liver.

In fact the fatty accumulation in the liver can be considered as equivalent to a moderate biliary obstruction which would explain the rise of phosphatasemia to levels lower than those seen in total obstruction yet higher than the ones found in hepatosis (3). This statement is further supported by the fact that lipocaic treatment decreases hyperphosphatasemia, but not always improves prothrombin figures. The latter occurrence speaks more in favor of a liver cell injury.

According to our observations on cholecystectomized dogs (3) the meaning of the initial hyperphosphatasemia seen in dog 561 is of different origin. The absence of fatty infiltration in this animal's liver suggests that in this case the transitory increase of blood phosphatase is due to a slight functional biliary obstruction caused by surgical interference. If it is remembered that the accessory pancreatic duct opens into the duodenum at the very level at which the common bile duct be-

Fig. 9.

Normal nucleus and cloudy cytoplasm in the process of disintegration (albuminoid degeneration). Some small necrotic foci in which the nucleus of cells has disappeared. Free to total cholesterol relation, 33.4 per cent.

Fig. 10.

Fig. 10. Dog 550. Normal appearance of the liver. Necropsy of this animal showed the persistence of the pancreatic duct accessory. Free to total cholesterol relation, 20 per cent.

comes intraparietal, this operative trauma will explain why there is a return to normal of phosphatasemia after 50 days just as in cases of cholecystectomized dogs. This effect should also be present in untreated dogs but when the time comes for it to disappear this does not take place owing to the fatty infiltration of the liver.

If our conception of the problem is correct the return to normal of phosphatasemia is a more accurate index for revealing the disappearance of the fatty infiltration of the liver under the action of lipotropic preparations than that of cholesterolemia, free to total cholesterol relation and phospholipemia. The disappearance of the infiltration should take place at least 50 days after the duct ligation. This fact agrees with the observation that phosphatase activity does not entirely return to the initial level at the time when the other blood components have become normal under the effect of the administration of our extract (dog 544, 51st day).

We believe that the persistence of a marked hyperphosphatasemia in dogs with pancreatic

ducts ligated more than 50 days before must be considered as an additional index of fatty infiltration of the liver.

Prothrombin. Our results show that in the dog the ligation of the pancreatic duct causes a liver injury revealed by a fall in the prothrombin concentration of the blood. This decrease cannot be attributed to a lack of vitamin K intake as treatment with 2-methyl-1-4 naphthoquinone did not improve the hypoprothrombinemia in accordance with the doses given. Instead the subsequent administration of lipocac proved to be far more effective.

The effect on hypoprothrombinemia of pancreatic extract administration became more evident in the treatment of early cases, but only in 2 of the 9 dogs we studied was it found possible to increase it to normal figures. In the 7 others, the response was either variable or never reached the subnormal concentrations, even though there was a return to normal of hypocholesterolemia and phospholipemia.

The persistence of hypoprothrombinemia after the normalization of the other blood

changes following the administration of the lipotropic extract and the shortlived initial fall in the prothrombin of dogs without fatty liver (dogs 661 and 550) seems to indicate that the variation of this blood principle is due not only to the presence or lack of fatty infiltration of the liver, but to some other cell injury that lipocaic does not repair altogether. Former experiments of ours (3) showing prothrombinemia as a more sensitive test for detecting the functional alteration of hepatocytes undoubtedly support this assertion.

Prothrombin increase after an injection of casein hydrolysate (dogs 621 and 671) appears to suggest the existence of a certain relationship between the hypoprothrombinemia and the protein deficit; however, further research is required on this point.

Proteins We have already remarked that the variations and response of proteinemia toward lipocaic administration are independent of those of the other blood components and vice versa.

The use of pancreatic extract as a corrective and preventive measure caused serum proteins to decrease both in animals treated early and in those untreated; moreover this decrease was unaffected by lipocaic administration. These results suggest that hypoproteinemia probably has its origin in deficiencies in protein digestion in the intestine brought about by ligation of the pancreatic ducts. In our experiments the results of investigations with casein hydrolysates dismiss the possibility of hypoproteinemia as a source of fatty infiltration of the liver. Evidently in dogs with ligated pancreatic ducts proteinemia and its regulating factors have no influence on the disorders of lipid metabolism and their repercussion on liver function.

With reference to the apparent potentiation of fatty infiltration of the liver by injections of casein hydrolysate, amino acid mixtures and glucose we cannot offer any plausible explanation. We believe that more purified preparations should be used in order to exclude the possibility of a toxic action by foreign substances.

Liver changes brought about in the dog by ligation of the pancreatic excretory ducts Macroscopical and microscopical examinations of

the liver show that in the dog ligation gives rise to a pathological fatty infiltration of said organ. Is this lesion an exaggeration of normal processes? It does not seem to be so as the said infiltration produces blood changes which reveal a considerable degree of liver injury.

Lipocaic administration corrects the liver infiltration provided treatment is started early; the later it is begun, the less pronounced is the improvement, thus a certain degree of liver injury remains.

A study of histological sections of the livers indicated that the functional disorder resembles that of a lesion with all the appearances of the reversible type. In the treatment of later cases, the impression remains that under more prolonged administration of the extract the function of the liver eventually becomes normal. With reference to this one should bear in mind the higher lipotropic efficacy of duplicating the effective minimum dose (dog 554 193rd day) and of systemic administration.

A point worth stressing is the presence of a type of lesion (Fig. 9) in which the cytoplasm of the hepatocyte appears cloudy and disintegrating (albuminoid degeneration); there are also some necrotic foci and karyolysis. From the pathological viewpoint albuminoid degeneration is considered as an alteration of the cell's proteic contents and it is often associated with a degenerative fatty infiltration (38). In this case (dog 671) such a lesion would explain the persistence of hypoprothrombinemia after the return to normal of cholesterolemia, free to total cholesterol relation and phospholipemia, following the administration of pancreatic extract.

We are unable to tell to what extent the pursuance of treatment will influence the return to normal of altered liver function and cell architecture. This subject requires further study.

Glycemia behavior We have purposely left the subject of glycemia to the end of our discussion as it is our opinion that glycemia is not influenced by the fatty infiltration process. In dogs in which the pancreatic ducts have been ligated, in all cases blood sugar remained within normal limits until the end of the ex-

PATELLECTOMY

A Simplified Technique

H. B. BOYD M.D., F.A.C.S. and BENJAMIN L. HAWKINS M.D. Memphis, Tennessee

THE increasing popularity of patellectomy together with the recognition of more frequent indications for the operation justifies the report of a simplified technique.

The general indication for patellectomy is a condition of the patella which impairs function of the knee joint or produces continued trauma to the joint surface and is painful. Patellectomy has been recommended for the following conditions: severe hypertrophic arthritis, traumatic arthritis, chondromalacia, osteochondritis dissecans, degenerative chondritis and old malunited fractures of the patella.

The technique to be described is not applicable in acute fractures or in old fractures of the patella which have not been repaired. The decision to remove the patella should be made before the operation as a capsular incision precludes use of this method. Sir Robert Jones was largely responsible for the split

patellar approach to the knee joint. This bisection of the patella is not recommended except when it is to be followed by excision.

Approach may be made either through a transverse or an anteromedial parapatellar incision. The skin and subcutaneous tissues are reflected thus exposing that portion of the extensor mechanism covering the anterior surface of the patella. The quadriceps expansion overlying the patella is then incised longitudinally in the midline. The incision is prolonged into the patellar and quadriceps tendons for the distance of 1 centimeter. The knee is flexed slightly and maintained in this position. The patella is grasped with towel clips on its medial and lateral sides in order to steady it while the operator sections it longitudinally with a saw (Fig. 1).

Care is taken to avoid introducing bone dust into the knee joint by careful cleansing of the wound just prior to completion of the patellar section. The patella is then elevated with the

Fig. 1. Anterior surface of patella has been exposed and the bone is being divided with a saw.

Fig. 2. Half of the patella is being enucleated from the extensor mechanism.

Fig. 3. The defect in quadriceps mechanism has been closed by plication.

towel clips in order to avoid traumatizing the cartilaginous surface of the femoral intercondylar notch as the section is completed with the saw or an osteotome.

One half of the patella is then grasped with a towel clip and positioned in such manner that the quadriceps expansion can be separated from the anterior surface of the patella by sharp dissection (Fig. 2). The other half is removed in like manner.

The anterior compartment of the knee joint can now be visualized for exploration or any additional surgery that may be indicated.

In closure of the extensor apparatus the edges may be simply approximated or imbricated with interrupted nonabsorbable sutures

of cotton or silk (Fig. 3). The remainder of the wound is closed in layers in the usual manner.

In methods of patellectomy which require a transverse closure of the extensor mechanism there is marked tension on the suture line making early active contraction of the quadriceps and flexion of the knee joint hazardous. The technique of patellectomy described does not produce a defect in the extensor apparatus or divide the capsule on either side of the patella. There is minimal tension on the suture line during active extension or flexion of the knee which permits immediate quadriceps setting exercises and early active motion at the knee joint.

COMMENTS

1. A simplified technique for patellectomy is described. This method has been employed in 10 cases.

2. The expansion of the quadriceps mechanism and capsule of the knee joint are not damaged.

3. Shortening of the quadriceps is not produced.

4. The defect in the quadriceps mechanism is minimal and can be closed in longitudinal direction.

5. Immediate postoperative quadriceps setting exercises and early active motion may be instituted without jeopardy to the suture line.

PROGNOSIS IN CARCINOMA OF THE BOWEL

R. K. GILCHRIST M.D., F.A.C.S. and VERNON C. DAVID M.D. F.A.C.S.
Chicago, Illinois

THE desirability of doing end-to-end anastomosis when resecting carcinoma of the colon or rectum is now one of the standard topics for discussion at surgical meetings. This paper will summarize some of our findings and may help you decide the proper procedure for each case.

Nine years ago we reported a method for the examination of surgically removed specimens of carcinoma of the colon and rectum.¹ By this method the specimens are made transparent, so that lymph nodes as small as one-half low power microscopic field ($\times 100$) can be identified easily. Full scale drawings of the specimens were made with accurate location of all of the lymph nodes. Microscopic sections of each node were made. We have studied about 325 specimens in this way and over 15,000 different nodes have been sectioned. The findings were similar in the entire series but this report will deal with the study of 200 of these patients who were operated upon 11 to 5½ years ago. Over 10,000 lymph nodes were sectioned in these 200 specimens.

Carcinoma spreads by direct extension by the blood stream and through the lymph system. If the spread by direct extension is great, the tumor is apt to be fixed to other structures. In the colon and especially in the sigmoid such fixation is often due to inflammation the tumor having extended much less than is at first imagined. This fact has justified the resection of contiguous organs. Spread by the blood stream seems to occur in 10 per cent to 15 per cent of operable cases as shown by Collier.

A study of our material has led to the conclusion that the lymphatic spread of carcinoma is primarily embolic, and that the nodes where cancer emboli lodge prevent further spread until the node is completely overwhelmed by carcinoma. Further embolic

spread is through the collateral lymph channels each new node involved tending to make a longer channel for a new embolus to travel. Spread from one node to another does not seem to be common at least during the period when lesions are seemingly operable.

It is possible to reproduce this picture of spread through the lymph system experimentally.² It is not difficult to insert a 27 gauge needle directly into the afferent lymph channels in a dog's mesentery. Similar injections can be made into lymph channels in a rabbit's ear or into lymph channels in the skin. We have made injections directly into as many as 14 different afferent lymph channels entering one node in a dog's mesentery. Many large afferent lymph channels break up into 2, 3 or more short channels just outside of the node and then these short channels pierce the capsule to empty into different parts of the subcapsular space or one of the short channels may empty into the lymph sinus of an adjoining node. In addition there are usually several different anastomosing channels between the large afferent channels draining a given region of the bowel and the channels draining into adjacent nodes on either side.

When a colored solution is injected into an afferent lymph channel of a dog's or rabbit's mesentery using very low pressure the solution will penetrate through the node without coloring all of it. The node seems to be divided grossly into separate anatomic units so that material from a given channel seems to drain to a limited part of the node. When pressure is used in the injection the entire node will be colored before any dye appears in the efferent channel. If instead of a colored solution a suspension of carbon particles $\frac{1}{2}$ to 1μ in diameter or of silica which is less than $\frac{1}{2} \mu$ in diameter or a suspension of barium or carmine particles is used to inject into the afferent channel using very low pressure a different picture is seen. The suspension of colored particles will partially fill its own com-

From the Presbyterian Hospital and the College of Medicine of the University of Illinois. Funds for this study were supported in part by the Otto A. Sprague Foundation.

partment in the subcapsular space (Fig. 1 A). If more pressure is used the suspension will either overflow into the remainder of the node or it will enter the adjacent parts of the node through one of the short channels leading into a different part of the subcapsular space (Fig. 1 B). If there is much pressure the node is soon a solid black and the suspension may pass into one or even two or three of the adjoining nodes through the short channels (Fig. 1 C). At the same time it may back up one of the tributary channels emptying into the original channel injected and it is often possible to get it to go through a retrograde anastomosing channel and come through another afferent channel into an adjoining normal node (Fig. 1 D). Even great pressure to the point of rupturing the walls of the afferent channels will not force any one of the fine suspensions through the node. If the animal is killed immediately or is allowed to live for a week and then killed no sign of passage through any node is seen, either in transparent preparations or in microscopic sections. This experiment shows very graphically how when a node is destroyed or blocked the lymph drainage is rerouted through collateral channels or by retrograde means into a channel draining into a normal node. Carcinoma cells are many μ in diameter in contrast to these particles which were all less than 1μ in diameter. The normal system of collateral lymph channels plus the demonstration of retrograde channels available when nodes are blocked shows how much more likely spread of the large carcinoma cells is apt to be by collateral channels than by growth through lymph nodes.

A study of our surgical material has brought out the following facts:

1. Permeation of carcinoma through lymph channels was seen only when the lymph node central to the channel involved was already blocked with carcinoma.

2. Carcinoma metastases do not completely destroy the function of a node until all of the node is destroyed. This was shown in a surgical specimen of carcinoma of the breast. The lymph channels in the neighborhood of the tumor were injected with a suspension of carbon particles. The specimen was cleared and some of the lymph channels and several

lymph nodes were seen to be outlined in black. This section shows how the carbon suspension could still flow into a node which contained a large metastasis. Most of the carbon is found in the normal part of the node although some of it penetrates a short distance into spaces between the cancer cells (Fig. 1).

3. Throughout the entire series a characteristic pattern of lymph node metastases was seen. The earliest metastasis was always found in the subcapsular space as in Figure 3. When the metastasis has grown larger than the small subcapsular lesion, the spread is by expansion around the subcapsular space and in the depth of the node. This expansion is usually accompanied by a thickening of the capsule especially over the area adjacent to the growth. There may be a more or less long layer of fibrous tissue between the cancer cells and the lymph cells. In many cases, there is so much interference with nutrition that we see a thick layer of fibrous tissue, a thin rim of live cancer cells within this, and necrosis in the center. Growth progresses until we see one or several large nodes, usually lying close to the main blood vessels, in which the lymphoid tissue is completely replaced by carcinoma. Groups of lymph nodes which are completely replaced by metastases tend to be found in certain regions. In specimens of carcinoma of the rectum and lower sigmoid, such nodes are usually located near the bifurcation of the superior hemorrhoidal artery (Fig. 4, No. 33779). In carcinoma of the breast, nodes about 1 inch below the brachial vein and along the lateral edge or just behind the pectoral minor muscle are the ones most likely to be completely replaced by carcinoma. The group of heavily involved nodes is along the main or primary line of lymph drainage. Nodes involved below or lateral to these nodes are apt to be subcapsular lesions or ones which are obviously late metastases.

4. In no case has there been any evidence of penetration of carcinoma outside of the capsule of any node except where there was a collection of large involved nodes lying tightly packed together. In cases in which this occurred the superior hemorrhoidal artery or the main artery supplying the region of the nodes was blocked by pressure of the nodes. Several

of these nodes contained necrotic material

5 In 7 cases retrograde metastasis to lymph nodes was found below carcinomas of the rectum. In every one of these enough of the nodes central to the lesion were completely replaced by carcinoma to make us feel certain that there was a very marked obstruction to lymph flow and the metastasis was by retrograde means (Fig. 4)

We will now study the 200 patients operated upon more than 5 years ago for carcinoma of the large bowel where there was a reasonable chance of cure (4). All of the surgical specimens were cleared and the lymph nodes were dissected under transillumination and the microscopically involved nodes were charted by the method described. The specimens used in this analysis were not always consecutive due to the work involved in the study of each one but were otherwise unselected except that the specimens from all fatalities were included. This results in somewhat higher mortality figures and lower 5 year survival rates.

These 200 patients represent an operability rate of approximately 75 per cent. Palliative resections for removal of tumor where known metastases could not be removed are not included in this group (Table I).

There is need for accurate anatomical location of tumors when discussing treatment of carcinoma of the rectum. The term *rectosigmoid junction* means different things to different surgeons. It can be located fairly accurately on proctoscopic examination. However it is impossible to identify on a surgical specimen. Roentgenologists often consider it a region 2 or 3 inches in length. This study has demonstrated the very different prognosis, recurrence and mortality rate to different regions of the colon. It seems to us that a new set of landmarks should be used. We have designated those carcinomas which are partially or completely below the peritoneal reflection as *extraperitoneal carcinoma*

Fig. Showing the manner of spread of a suspension of insoluble particles injected into a single afferent lymph channel

of the rectum. There were 112 of these. Those lesions which are entirely covered by peritoneum anteriorly and which are below the promontory of the sacrum should be designated as *intrapertoneal carcinoma* of the rectum. There were 41 of these. Fourteen were in the redundant loop of sigmoid above the promontory of the sacrum. (These last 2—total of 55—will be grouped as one in this discussion as all findings were identical). Fifteen were in the right colon which included the cecum, ascending colon, hepatic flexure and the first 3 inches of the transverse colon. Eighteen were in the left colon which included all of the remainder of the colon to the redundant loop of the sigmoid.

One hundred and twelve tumors were partially or completely below the peritoneal reflection. There were 12 postoperative deaths and 4 had no follow up. Only 26 of the 69 with node metastases were alive after 5 years (37.5 per cent) whereas 32 of the 43 without

TABLE I.—200 CASES OF CARCINOMA OF THE COLON AND RECTUM

Incomplete follow-up	7	3.5

Fig. 2

Fig. 2. Photomicrograph of lymph node almost completely replaced by carcinoma metastases. The normal parts are seen as dense, finely granular areas. A suspension of carbon particles was injected into the lymph channels in the neighborhood of the carcinoma of the breast. Most of the carbon is seen in the normal part of the node, although some of it penetrates a short distance along spaces

Fig. 3

between the cancer cells. A part of the lymph node which is involved with carcinoma also contains carbon particles. Areas of fatty degeneration are seen.

Fig. 3. Photomicrograph of carcinoma metastases which is confined to the subcapsular space. The thick capsule lying over the region of the metastasis is clearly demonstrated.

node metastases were alive 5 years (74.4 per cent)

Of the 69 with node metastases 30 or 43.5 per cent developed recurrent carcinoma in less than 5 years while only 5 or 11.6 per cent of the 43 without involved nodes developed recurrent carcinoma.

The incidence of local and liver recurrences in these low lying tumors is striking. If we subtract from the 69 with involved nodes the 16 patients who either died postoperatively in the hospital or were lost to follow up or those who died of other causes where there was no recurrent carcinoma the figure for local recurrence will be more than 30 per cent and almost 20 per cent for liver recurrence.

TABLE II.—112 EXTRAPERITONEAL RECTAL CARCINOMAS

Of 43 without node metastases alive 5 years	3	74.4

Fifty five tumors were entirely above the peritoneal reflection. Fourteen were in the sigmoid and 41 were below the promontory of the sacrum. All findings were identical and these were grouped to save space. The favorable prognosis in this group and especially in those without lymph node metastases (60 per cent) is striking (Table IV).

Twenty seven of the 55 patients had obstruction resections performed. In many the extraperitonealization of the resected area was done as described by David. In the more unfavorable cases abdominoperineal resections were performed. This probably accounts for

Fig. 4. Path No. 53779. This is operative specimen showing metastases to lymph nodes 4 centimeters below the carcinoma. The amount of each node replaced by carcinoma is shown in black. The largest nodes are 4 millimeters or more in diameter. A mass of large necrotic carcinomatous nodes caused almost complete occlusion of the superior hemorrhoidal artery just above its bifurcation.

the fact that the results with obstruction resections were about the same as with the abdominoperineal resections. Of the fifty-eight 18.1 per cent died of recurrence within 5 years the recurrence rates being similar in the 2 types of operations. The low incidence of recurrence here contrasts sharply with the 43.5 per cent seen in tumors which are extraperitoneal.

Fig. 5. No. 36682. A 64 year old man who had had symptoms for 3 months. This tumor was grade III Broder's and Duke's C. He developed a local recurrence in the hollow of the sacrum within 6 months. This finding of metastases in nodes high above low lying tumors is not uncommon even when only a few involved nodes are present. This seems to re-emphasize the necessity for wide resection of mesentery even when there are no palpably enlarged nodes.

Resections of the 33 patients with carcinoma proximal to the sigmoid colon were done by several different surgeons. Twenty-one had lymph node metastases (63.6 per cent). Twenty were alive 5 or more years (60.6 per cent).

Fifteen were in the right colon, all had ileo-transverse colon anastomoses at the time of resection. Thirteen or 86.6 per cent of these had metastases to nodes and in spite of 3 postoperative deaths and 1 lost to follow up 9 were known to be alive after 5 years (61.5 per cent). These operations were performed before the era of chemotherapy therefore the operative mortality in this group would be lower at this time.

Eighteen tumors were in the transverse or descending colon. Only 8 had node metastases.

TABLE V — RECURRENCES IN 55 INTRAPERITONEAL TUMORS

Lung or general	2		3.6
Total	10		18.1

Fig. 6. No. 4177 Seventy two year old man who had had symptoms for 4 months. The surgical specimen contained 46 lymph nodes. Fourteen of these contained metastases. He died of pneumonia. The autopsy specimen contained 14 lymph nodes. Four nodes above and one node just lateral to the field of resection contained metastases. This is an example of metastasis laterally along the levator ani muscle as well as up and along the superior hemorrhoidal artery. In spite of a very large tumor the lymphatic metastases are localized to an area which could have been resected.

(44.4 per cent) This is the lowest incidence of involved nodes seen. Five of these 8 died of recurrence within 5 years. Only 3 of the 8 lived 5 years (37.5 per cent) in contrast to 80 per cent of those without involved nodes. All of

these had obstruction resections. There were no postoperative deaths and one was lost to follow up. This suggests that resection in this area has been too conservative.

Fig 7 No. 36903 A 63 year old man who had had symptoms for more than a year. Biopsy was made of this carcinoma 12 months before, but he had refused operation. The tumor was ulcerating and it had penetrated all coats of the bowel. Nodes were palpable in the hollow of the sacrum. Sixty-two nodes were found in the surgical specimen. 43 of them showed metastases. He died of a pulmonary embolus on the eighth postoperative day. One hundred sixty retroperitoneal nodes were examined microscopically. In spite of the extensive lymph node involvement, there were no metastases above the point of resection. The one node involved was about 1 centimeter lateral to the widest point of resection along the levator ani muscle.

The surgeon gave a guarded prognosis at the time of resection because of grossly enlarged lymph nodes in 55 of the 200 cases

Table VIII indicates the prognosis in those having palpably enlarged nodes proved to have metastases on microscopic section

Fig. 8. No. 36642. A 72 year old man. II had had symptoms for 6 months. The surgical specimen contained 35 nodes and 7 of these contained metastases. II died of bronchopneumonia. One hundred eleven nodes were studied in the postmortem preparation. 4 contained carcinoma. The highest metastasis was in node found at the junction of the inferior mesenteric artery and aorta.

Small scars (grains of sand nodules) were palpated in the liver in 11. These were too small and indefinite to be considered metastases. Eight lived 5 years. One died after operation. One developed a local recurrence and one who had no recurrence died of diabetes. These small lesions are usually almost of one size and the occasional operator should not be influenced adversely when they are found (Table IX).

Thirty five of the 200 patients required resection of all or part of other structures because of firm fixation of the tumor (Table X).

TABLE IX. — POOR PROGNOSIS DUE TO SUSPICIOUS NODULES IN LIVER — 11

	Number
Alive 5 1/2 years	8
Died in less than 5 years	3
Postoperative death	1
Local recurrence	
Diabetes, not carcinoma	

Fourteen or 40 per cent of these patients were well 5 years. This figure would be higher today as 7 or 20 per cent died after operation. This mortality would be favorably influenced by chemotherapy. Wide excision of structures adherent to the tumor is justified by these findings.

Seven patients having carcinoma below the promontory of the sacrum had metastases to lymph nodes distal to the tumor. Such metastasis occurs when there is lymphatic blockade. This finding re-emphasizes the necessity for extensive resection in those having enlarged nodes and large tumors.

Abdominoperineal resections of the rectum were performed in 140. Four of these were two stage resections. In 2 resections of other structures made a mass of tissue too large to pull through the pelvic outlet in the male and in these the rectum was cut off just above the anus and the stump was closed. In all of these

Fig 9. No. 37719. A 66 year old fat man. He had had a known coronary thrombosis 10 months before. The lesion was 1 inch above the peritoneal reflection. It was the size of a fist and there was a mass of nodes extending to the promontory of the sacrum. A David type of obstruction resection was performed. He died 14 days after surgery of myocardial failure. One hundred sixty-eight nodes were found in the postmortem preparation. The one involved node was less than 1 cm. beyond the line of resection.

there was an average of 55.3 nodes per specimen sectioned and studied microscopically. One specimen contained 210 nodes and 6 had 112 or more nodes each. Those having an obstruction resection of the sigmoid or intra-pentoneal rectum averaged 41.6 nodes per

specimen and one specimen contained 102 nodes. Specimens from obstruction resection of the left colon averaged 40 nodes each and one had 69 nodes. Specimens of the right colon obtained by resection and primary ileotransverse colon anastomosis averaged 54 nodes

each with one having 115. Seventy two of the 125 specimens having metastases to lymph nodes had 4 or less nodes involved per specimen

In low lying carcinomas of the rectum small high lying lymph nodes not uncommonly are found to contain metastases. Specimen No. 36682 is typical of such cases and serves to re-emphasize the fact that the widest possible resection of the mesentery is needed to give a chance of permanent cure (Fig. 5).

Four or less involved nodes in 72 of 125 with involved nodes (Table XII).

Three patients were pregnant when the carcinoma of the rectum was discovered. Two have long time cures (Table XIII).

The first and third patients had full term deliveries 1 or 2 months before surgery. The second patient had an abortion at 4 months.

New carcinomas have developed in 7 of the 200 patients. In each of these cases there is very strong evidence to suggest that these are new tumors and not metastases (Table XIV).

The patient with a previous resection, either with or without a colostomy must be watched carefully or these new tumors may cause almost complete obstruction before they are discovered.

When there is a double blood supply to the region of the tumor there is usually a double lymph drainage. We have a number of instances of carcinoma at, or just below the peritoneal reflection in which we have found metastases to small nodes about 2.5 centimeters lateral to the bowel wall, along the superior surface of the levator ani muscles. Also, either squamous cell carcinoma or adenocarcinoma involving both the mucosa and the perianal

skin may have metastases upward to nodes along the superior hemorrhoidal artery as well as to the inguinal nodes. In some cases both groups have been involved. This must be considered when planning surgery.

If we exclude those patients who have died of other causes without any sign of recurrent carcinoma and those who had no follow up and those who died postoperatively the prognosis would be as shown in Table XV.

The most striking finding here is in those tumors of the transverse colon, splenic flexure and descending colon where nodes were involved. All of these had obstruction resections and only 3 of the 8 (37.5 per cent) were alive 5 years. The widest possible resection is indicated here rather than the usual V shaped wedge of mesentery resected. The favorable prognosis (77.7 per cent) seen in right colon lesions having involved nodes is undoubtedly due to the wide resection of mesentery (54 nodes per specimen) performed when doing an ileotransverse colon resection and anastomosis.

Nineteen died in the hospital after surgery. Eight had no postmortem examinations. Three had postmortem examinations and the usual search was made for metastases to retroperitoneal nodes but none were found al-

though all three had had lymph node metastases in the surgical specimens.

In the remaining 8 all of the retroperitoneal tissues from the celiac axis (Fig 6 No 41772) to the base of the bladder and prostate were cleared and 96 to 168 lymph nodes (Fig 7 No 36303) were examined in each. Two who had no nodes involved in the surgical specimen were free of metastases in the cleared

Of 10 left colon without involved nodes	8	80.0

postmortem preparation (Fig 8 No 36642) Four who had metastases in the surgical specimen also had metastases in the cleared specimen. In 3 of these 4 (Fig 9 No 37719) the involved nodes remaining after surgery could have been removed if the resection had been 15 centimeters wider! In one a resection of all of the inferior mesenteric artery would have been needed to remove all involved nodes (Fig 10, No 37719-139) These findings re-emphasize the fact that we must not limit the resection of lymph node containing tissue in carcinoma if we strive for permanent cure.

CONCLUSIONS

1 In this study of 200 patients having resection for carcinoma of the colon there was a 96.5 per cent 5 year follow up. One hundred and fourteen were known to be alive 5 to 10 years (57 per cent). In the study of the surgically removed specimens, microscopic sections were made of over 10,000 different lymph nodes, carefully plotted as to location to tumor and surgical landmarks. A number of facts stand out.

2 There is a real need for uniform and accurate description of the location of the tumor when discussing the value of different operative procedures in carcinoma of the colon and rectum. We have suggested an easy and accurate method for locating those tumors below the promontory of the sacrum.

3 Cases of palliative resections where known metastases are left in the liver, lung, etc., should not be included in discussions of surgery for cure of carcinoma, since the inclusion of such cases tends to confuse the reader.

4. The 37.5 per cent 5 year survival rate of those having carcinoma of the left side of the colon when lymph node metastases were present indicates the need for the widest possible resection of mesentery rather than the usual V-shaped wedge of mesentery resected in these cases. The favorable prognosis seen in right colon lesions having involved nodes is undoubtedly due to the wide resection of mesentery (54 nodes per specimen) performed when doing an ileotransverse colon resection and anastomosis.

5 Retrograde metastases to nodes 1 to 3 centimeters below the tumor occurred in 7 of the 153 tumors below the promontory of the sacrum (4.6 per cent).

6 New carcinomas developed in 7 patients who had had resections. This does not include carcinoma of the skin. In some, the diagnosis was not made for several months after symptoms appeared. Patients who have had cancer of the colon should be re-examined carefully whenever any symptoms suggesting carcinoma appear.

7 In evaluating the type of procedure used in treating carcinoma the survival rate is important. Of those who died of recurrence less than 5 years, two-thirds occurred within 3 years and one third between 3 and 5 years. Six of those listed as 5 year cures developed recurrences and were dead or dying in less than 7 years. In view of the appreciable percentage who develop recurrence in the fourth and fifth year after operation, it seems unwise to consider anything less than a 5 year survival as a cure. Such short term survivals should not be included in discussions since they lead the general practitioner to false conclusions.

8 In carcinoma at and below the peritoneal reflection where lymph node metastases were present in the surgical specimens, 23.9 per cent developed local recurrences and 15.9 per cent developed liver recurrences within 5 years.

9 Postmortem examination of those dying in the hospital after resection for carcinoma of the rectum showed that the ordinary postmortem examination will usually fail to demonstrate small metastases in the remaining retroperitoneal lymph nodes. Four of 11 who had postmortem examinations were found to have metastases to nodes in the retroperitoneal tissues. In 3 of these, complete removal of all node metastases would have been obtained if the field of resection had been 15 centimeters wider. It is interesting to speculate on the fate of the cancer cells left in these nodes had the patient lived. In some, inflammation might have resulted either in death of the cells or fixation in heavy fibrous tissue. It is not unlikely that such metastases in lymph nodes mislaid at operation finally grow. They might grow to great size without giving symptoms.

We have sections of the blood vessels supplying involved lymph nodes being invaded by cancer. Possibly emboli from such a source might be responsible for the sudden appearance of multiple metastases many years after resection of the primary growth.

Finally this study indicates the need for the widest possible resection in carcinoma of the colon. Lesions which are partially or completely below the peritoneal reflection have a high incidence of local and liver recurrence. The Miles operation seems to give the best chance of cure here.

As far as lesions within the peritoneal cavity are concerned, we have performed obstruction resections on several in this series that could be palpated when doing a rectal examination. This is justified if not only the bowel wall but the blood vessels and lymph bearing tissue are resected at least $1\frac{1}{2}$ to 2 inches below the lesion as well as to a point just distal to the first sigmoid artery: this is a point about $1\frac{1}{2}$

to 2 inches above the promontory of the sacrum. If such resection is not done involved nodes will be missed. The David extraperitoneal procedure will allow for such a resection in many. If after such an extensive resection of mesentery there is still an adequate blood supply to the distal loop we do not object to an end to end anastomosis. The real question in the discussion about end to end anastomosis is missed: it seems to us. It should be: Can you remove all of the cancer? and not: Can you sew two ends of bowel together? Obviously in those intraperitoneal lesions below the promontory of the sacrum which are large or have palpably enlarged nodes the abdominoperitoneal resection will give a greater chance of cure.

ESOPHAGITIS

IN recent years much has been written concerning diseases of the esophagus. Carcinomas of the esophagus are found rather commonly and thoracic surgeons are performing resections of the esophagus for this condition with increasing frequency. Many articles are appearing in the literature concerning the therapy of cardiospasm, congenital anomalies, cicatricial strictures, diverticula and benign tumors of the esophagus. Such topics as functional dysphagia, the Plummer-Vinson syndrome, esophageal perforations, foreign bodies and esophageal varices have received their share of consideration.

Although the aforementioned conditions have been discussed rather widely, esophagitis is a subject that has not received the attention it deserves in medical literature. A number of years ago Vinson and Butt¹ stated that esophagitis occurs more frequently than does any

other condition which affects the esophagus. In the course of some 3,000 necropsies they found evidence of esophagitis in 7 per cent of the cases. Yet in the review of the records of these patients they found that symptoms of esophagitis were recorded in only 10 per cent of the group of patients who subsequently were found to have inflammation and dilation of the esophagus. Apparently esophagitis is a condition which is seldom recognized during a patient's life. Paul² has stated that acute ulcerative esophagitis is a common finding at necropsy but rare in clinical practice.

Esophagitis is a condition that should be of great interest to the surgeon. It usually occurs in patients who have diseases which require surgical treatment or in patients who have undergone major surgical operations. Vinson and Butt found that in 75 per cent of their 213 cases of esophagitis the patient had been operated upon a short time before. The disease is encountered most commonly in patients who have gall bladder disease, duodenal ulcer,³ obstructing lesions of the gastrointestinal tract and esophageal hiatal hernia. Selye⁴ was able to produce hemorrhagic esophagitis by ligating the pylorus in experimental animals. In some instances, esophagitis appears to follow severe infections of the upper part of the respiratory tract.

Why does esophagitis occur? Certainly a number of factors are involved and deserve consideration. The trauma caused by the passage of nasal tubes may predispose to esophagitis. Certain abdominal conditions and operative procedures require that such

¹Vinson, P. P. and Butt, H. R. *J. Am. M. Ass.*, 136, 66 (1940).

²Paul, L. W. *Radiology*, 94:4, 421-430.

³Benedict, E. B., and Daland, E. M. *New England J. M.*, 1938, 309-307.

⁴Selye, Hans. *Canad. M. Ass. J.*, 1938, 39: 477-484.

tubes remain in place for a considerable period of time. However, I doubt very much that introduction of nasal tubes alone is often responsible for serious esophagitis although in the presence of pre-existing esophagitis it may do a great deal of harm.

Attention should be called to the occasional occurrence of perichondritis and stenosis of the larynx as a result of use of a nasal tube in the esophagus. Strictures in the vicinity of the cricoid cartilage are particularly susceptible to the pressure effects of such tubes. Although the use of nasal tubes is a valuable adjunct to the therapy of some abdominal diseases these tubes should be used with discretion and for as short a time as is possible.

More commonly esophagitis is caused by the reflux of gastric secretions into the esophagus. These digestive juices are very irritating to the esophageal mucosa. Esophagitis is likely to occur in association with abdominal diseases that produce excessive vomiting. In competence of the cardiac sphincter likewise results in regurgitation of gastric acids into the esophagus. The cardiac sphincter is in competent in many cases of esophageal hiatal hernia and esophagitis frequently is associated with hiatal hernia. Years ago Harvey Cushing¹ called attention to the frequent occurrence of esophagitis and esophageal ulceration in patients with lesions of the brain. Pathologists often describe ulcers of the esophagus in cases in which death was due to brain tumor.

The symptoms of esophagitis frequently are overlooked. Such terms as "heartburn" and "sour stomach" often are used by patients to describe a substernal and epigastric burning sensation caused by inflammation of the lower part of the esophagus. In cases in which the disease is severe patients may complain of substernal pain sometimes referred up to the

throat and neck and even into the arms. Such pain usually indicates esophageal spasm and some of the cases fall into the category described by Moersch and Camp² as diffuse spasm of the esophagus. In such cases severe dysphagia may develop. Of interest is the work of Dey and his associates³ who demonstrated that reflex spasm and shortening of the esophagus may be produced in experimental animals by stimulation of the vagus nerves by manipulation of the stomach, liver and other abdominal viscera and by distention of the gall bladder.

In cases of severe ulcerative esophagitis hemorrhage may occur. In their series of cases in which necropsy was carried out, Vinson and Butt found that 32 of 213 patients had presented symptoms of esophagitis. Of these 32 patients 53 per cent had complained of substernal burning, 40.8 per cent had had hematemesis and 28 per cent had complained of difficulty in swallowing. In view of the fact that in all of Vinson and Butt's cases necropsy was performed, they are not representative of the usual cases seen clinically. The majority of patients who have undergone operation will not describe symptoms of esophagitis unless careful inquiry is made.

In most cases esophagitis probably subsides without leaving any ill effects. However, repeated episodes of esophagitis lead to a progressive cicatrization of the lower part of the esophagus. Recently Harrington and I⁴ have shown that an actual shortening of the esophagus may occur with stricture at the esophago-gastric junction. Repeated episodes of ulcerative esophagitis and healing of the esophagus are usually responsible for the short esophagus type of esophageal hiatal hernia. This condition most commonly occurs in association

⁴Cushing, Harvey. *Surg. Gyn. Obst.*, 1911, 55, 34.

with duodenal ulcer gall-bladder disease and other abdominal diseases which produce regurgitation of gastric secretions. Esophagitis and shortening of the esophagus may develop in cases of hiatal hernia because of reflux of gastric acids into the esophagus. In cases of short esophagus with intrathoracic stomach usually the shortness is not congenital. Shortening is caused by recurring ulcerative esophagitis and is frequently secondary to surgical lesions of the abdomen. The conclusions reached by Harrington and me were similar to those reached by Allison¹ and by Smithers.²

The fact that esophagitis is not an uncommon complication of disease of the upper part of the abdomen must be recognized. When surgical intervention is indicated it should not be delayed. Gastric secretions should be neutralized with antacid preparations in cases in which these secretions are regurgitated into the esophagus. At times elevation of the head of the patient's bed is helpful in preventing a reflux of gastric acids. In the postoperative period inquiry should be made concerning symptoms suggestive of esophagitis. Nasal feeding tubes should be used with some discretion when the presence of esophagitis is suspected. Sometimes esophagoscopy is indicated. If cicatrization and stricture occur relief of dysphagia usually can be obtained by dilatation performed over a previously swallowed thread.

ARTHUR M. OLSEN

PREPUBERTAL MELANOMA OF SKIN

however seems to proceed after birth with exposure to light. In other words, the elaboration of the pigment does not seem to occur greatly *in utero*. By the time the child is a few years old these tumors become much darker in color. Many of them do not increase in dimension except proportionately with the rate of the growth of the child. It is evident in studying the phenomena of the development of pigmented nevi that many of these nevi are not at all visible until after the onset of puberty. A child with a few scattered pigmented moles here and there may in company with the endocrine changes attendant on the state of puberty have the rather sudden development of numerous pigmented nevi over the skin of the face, trunk and extremities. It is assumed that these are not new-growths, in the strict sense of the word, but that the congenital misplacement of these cells may have been present but unrecognized until influenced by the hormonal factors so increased at this time. The nevi also undergo some remarkable pigmentary changes with the onset of puberty in that they become much more darkly pigmented and have a tendency to become elevated above the level of the surrounding skin.

There is one important type of pigmented nevus which bears such a close resemblance to malignant melanoma that it is not possible, clinically, to distinguish between the two. This nevus may be found in children from ages of one to the time of puberty. Usually they are rather darkly pigmented, bluish, blue, black, or dark brown in color, smooth and well

tered in adults. Even though the tumor has structurally the conformation of the true melanoma it ordinarily does not behave as such until after puberty. Our experience with now more than nine hundred cases of malignant melanoma has been that none of these melanotic tumors of infancy and childhood has metastasized to regional lymph nodes although many of them have been labeled as malignant melanoma by extremely competent pathologists. This fact is now so well recognized that our pathologists insist on having clinical information available concerning the age of the individual and whether or not evidences of approaching puberty exist. For example a diagnosis of juvenile cellular nevus may be made on a tumor excised from an adolescent boy only to discover some months later that inguinal lymph nodes contain metastatic melanoma the youth showed evidences of pubertal changes. We might well adopt such a term as *prepubertal melanoma* to indicate the group of tumors which resemble malignant melanoma histologically but do not behave as such.

It is our belief therefore that the malignant melanoma in its derivation from the pigmented nevus is a tumor closely related to the endocrine system and markedly influenced by the activity of the endocrines notably the gonads, the suprarenal cortex, and the hypophysis. In keeping with this opinion, we have often observed malignant melanomas to occur in adolescent girls and boys just after the age of puberty and furthermore we have commented on the extremely rapid growth and wide dissemination of these tumors at this early age. Apropos of these statements concerning the stimulation of the tumor by hormones, it may be mentioned that we have never seen a patient who developed a malignant melanoma during pregnancy survive for any length of time. We have had quite a

number of instances in which a pigmented nevus underwent malignant degeneration into melanoma during pregnancy or shortly thereafter and when this occurred the tumor grew with startling rapidity and was usually widely disseminated without control by surgical excision however radical or by any other methods of treatment.

The significant conclusion to be drawn from these observations is the obvious necessity for complete surgical removal of all dark deeply pigmented nevi in childhood. Their removal in infancy and childhood entails very minor surgical procedures without the hazards of recurrence. It may be a serious mistake to delay this operation until some evident change has occurred in the appearance of the tumor sufficient to cause worry particularly if this change develops at the time of or shortly after puberty. In reviewing the end results of the treatment of melanoma at the Memorial Hospital the number of 5 year survivals without recurrence (definitive cures) was only 50 per cent as good in the group of patients whose ages extended from puberty to 25 years as it was in the older age group. A microscopic diagnosis of melanoma in a skin tumor removed during infancy and childhood does not call for an extension of radical surgery such as wide excision and skin grafting and dissection of regional lymph nodes, provided the child has not entered the pubertal stage. This last statement is based solely on our personal experience at the Memorial Hospital in a series of more than 900 malignant melanomas. When we investigated the rumored instances of metastasizing prepubertal melanoma from other hospital sources we encountered only one instance in which the sectioned lymph node contained apparent melanoma cells in the other instances the tumors were bizarre and of uncertain histogenesis.

BELLS TOLL FOR PRIMES

An Inquiry into the Fate of William the Conqueror

FRANCES TOMLINSON GARDNER San Francisco California

THE deathbeds of personages of historical importance are pried into with the enthusiastic curiosity of small boys turning over a dead lizard. Human nature enjoys meditation on the fact that the last mortal moments of the great are very similar to and no more comfortable than those of the common herd. It is pleasing to learn that the mighty of the past, though surrounded by voluminous soiled velvet and many dented golden vessels, still writhed on the same old bed of pain.

So William the Conqueror met death. Praying, declaiming and groaning, he departed this life on the 9th of September 1087. In the depths of the Middle Ages when medical observation was at its lowest ebb and his devoted attendants so consumed by their eagle-eyed watch for the devil or any hovering angels that their interest amounted to espionage. They remembered every word of his remarkable deathbed discourse and were admiringly attentive to the manner in which his departing spirit met its Maker, but all they knew about his illness was that he was very stout, had gotten very hot and tired and had bumped into the pommel of his saddle. They gave never a thought to what, in William's life, food habits, and manner of living bore upon his painful end, or what mechanics of the body caused that end.

He was born in the last month of 1027 or a very early month in 1028 to Robert, Duke of Normandy and his mistress, Harleve, also called Arlette, the beautiful daughter of the local tanner. His father somewhat vividly known as Robert the Devil, died at the age of 35 in the traditional best manner while on a pilgrimage to the Holy Land. His mother taking his little sister Adeliz by the hand, soon went off to marry Herlewin of Conteville, by whom she bore two half brothers for

William and Adeliz. These were trying and turbulent Odo, later Bishop of Bayeux and Earl of Kent, and Robert, Count of Mortain, just a normal unimpressive relative.

In his youth and middle age William was stocky but well proportioned with a neck somewhat longer than the average and shoulders so wide and powerful that even in his waning years he could pull, while seated on his horse, a long bow too heavy for his archers standing on the good firm earth. His life was one spent in fighting, brawling and battle, but in spite of all to which his body was subjected no mention is made of any wound or debility until he was a man in his fifties, a comparatively ancient age for the eleventh century. He was, by nature, an aggressive extrovert. He was ruthless, brutal, stern, frightening, kind, gay and loving all to an extreme degree. In the interests of his position in life he cultivated an expression of ferocity which went well with his high bald forehead and which frightened away much weak-hearted opposition.

Dietetically he was seasonal, which was forced upon him and all his fellows by the ignorance of the times. In the good months of the year he ate his beef, boar, venison, and mutton for breakfast, lunch, and dinner. Since his kitchen contained nothing that would approximate a modern stove his meat was roasted on a spit turned by a half-hearted kitchen boy and served red and dripping. Consequently though not very hygienic and frequently full of parasites, it presented his inner economy with all its available vitamins. He partook occasionally of chicken, and very reluctantly on fast-days, of fish. He refused to have much to do with the few vegetables of the time, frowning on them as women's fare, but he could be coerced into real enjoyment of a 'mortreux'—a meat and vegetable stew, provided it was fancily dressed and accompanied by plenty of rich sweet

From the Department of Medical History and Bibliography
University of California Medical School, San Francisco.

liquor usually mead. His flour made up into large round loaves or served as his favorite dessert, bag pudding a kind of forerunner of modern apple pudding was roughly ground and often unbolted and retained all its useful vitamins. His garden supplied him with wizened but succulent little plums, apples, and pears for a finish for his gigantic trencherings.

The picture was very different in the winter. All the meat was crudely dried, salted, or pickled. There were few if any vegetables. The fruit was gone and the flour was damp and moldy. William ate so badly that he like all his people met the return of spring with his annual touch of scurvy as commonplace in those days as spring fever. William ate of the fat of the land, but in cold winter the land was, indeed, not very fat.

William may have had trouble with constipation brought about by a combination of such things as diet, winter restrictions on his customary exercise, and the lack of reasonable hygienic arrangements about his castle. I do not mean to infer that anyone of the period was squeamishly modest, but icy cold castles can force a certain added reluctance on a sluggish colon. William may have built up a strong tendency to a condition which, as his years grew longer could well have become chronic.

Somewhere between his fortieth and his fifty-ninth year serious changes took place within the previously impervious body. He grew corpulent out of all proportion to his build and in 1086 when he was about 58 was forced to take to his bed, in Rouen under care of what physicians were available, for the reduction of his "corpulence." This obesity seems to have been genuine fat, honestly come by since nowhere is there mention of tapping or of water logged tissues. Had there been there would have been comment, because if there was any condition an eleventh century doctor could recognize it was the presence of edema. By the process of eliminating other things excluded by William's physique and activities and the silence of his contemporaries we can omit ulcer, cancer, hernia, heart and kidney disease. However it is not in the character of such a man to lie meekly in an uncomfortable bed for several weeks when enemies all around him might take advantage of his impotence so that something greater than simple adiposity forced him to give up.

It is a fair guess that William was suffering from diverticulitis of the colon. It would be impudent of an author writing today using the little information which is available, to declare just where the diverticula might be or whether there were many of them. Perhaps it is presumptuous even

to suppose that he had them, but his 172 lb. vague distress, his grossly fat body and his probable chronic constipation clamor their acceptance of the condition. A long history of epigastric discomfort which evidently also had long periods of remission and comparative comfort, coupled with no history of anything startling in addition, points to a comparatively asymptomatic diverticulosis which gradually becoming more and more unmanageable, finally put William to bed. It is a predicament which, in its subtle obscenity would unquestionably baffle an eleventh century physician whose treatment could consist of little more than emetics, purges, and bed-rest.

While he was reposing at Rouen his own Philip King of France, found time to be cross about him. In public, Philip remarked that he was surprised that his Brother England should be so long a time in being delivered of his big boy. This uncouth insult was promptly conveyed back to the sick room where its effect was volcanic. William was not devoted to Philip at any time but had a little bone to pick with him in the matter of the Vexin a province once his own which, through many involved negotiations between vassals and overlords, had been annexed by Philip. For 10 years William had been too busy to get it back again but now he seized upon the old quarrel as a pretext to retaliate for Philip's spiteful comment which William interpreted as likening him to a woman lying-in. He rose from his bed with a roar exclaiming that, at his churching, he would set all France ablaze. This cryptic statement referred to the custom of a woman carrying a candle to her churching after childbirth. William would allow no one, least of all the King of France, to suggest that he was womanish.

The last week of July 1087 he appeared suddenly before Mantes which he besieged and, on the 10th of August, took. On entering, his orders to his troops were "scatter, pillage, and burn," which they obeyed to the letter. They removed everything movable and burned everything inflammable, including the churches and the standing corn. The huge, sick, old man rode everywhere, shouting and scowling. The summer heat was torrid and the flames from the burning buildings added nothing to the comfort of man or beast. William's horse, weary from the enormous weight of its rider heavier than ever because of his anorexia, excited by the flames and guided by a careless hand, stepped upon a burning ember. It was said solemnly at the time, that God caused this to happen as punishment for the terror visited upon the town. Doubtless William deserved the punishment but it is more likely that God was out-

piled elsewhere and that the flaccid old body taken by surprise could not counter the startled leap of the charger. He was flung against the high hard pommel of his saddle and something serious happened within him.

He was carried back, by litter to Rouen. Physicians arrived in the persons of Gilbert Mamnot, Bishop of Lisieux, and Goutard, Abbot of Jumièges with some others well skilled in medicine. These learned and holy counsellors hovered around his bed during all the few weeks which remained of his life hung adoringly on each word of his noble and long winded confession and oration which filled his last days, exorcised his spiritual devils, and seem to have entirely omitted to bother about his physical ones. Word for word of his conversations with his sons, his bequests of his substance his speeches to the holy family have been given us but neither Gilbert nor Goutard left so much of a clinical note as 'vomited or fevered'

He languished at Rouen. The heat was terrible as were the stinks and flies of that medieval city. So were the shouts and cries of peasants and market folk and driven cattle and all the thousand noises of the narrow streets. William asked to be taken to the church of St. Gervase which lay a short way out of the city. His physicians agreed to the brief journey and he was installed in the priory there where breezes blew away some of the heat and the only noise was made by the quiet steps of soft footed monks.

During the 4 weeks of his dying William's mind was as clear as his body was agonized. In his famous deathbed oration which must have continued daily for most of the period of his last illness, he confessed to all his sins and depredations, apologized to those he had wronged and begged the forgiveness of the church for all he had done against it, none of which of course had he done intentionally. He called his sons William Rufus and Henry to his side and gave them his bequests in his own voice. Robert, the eldest was in Germany. William gave him the Norman inheritance with the peevish remark that Robert was a 'proud and silly prodigal and will have long to suffer severe misfortune.' He did not care for Robert. England went to William Rufus who was admonished to be less a king than a watchful servant of God. William was a little ashamed of the way in which he had acquired England himself and felt that he should make some amends for his behavior. William Rufus was dispatched to England on the day before his father's death to study under the good Bishop Lanfranc, how to be a good king. What success Lanfranc had in his teaching can be

read in the history of Rufus reign which was of such cruelty and terror as to make William's sins seem lily white.

Henry the third son was given only money. This brought a wall from Henry who said that 5,000 pounds was nothing if he could not have a corner of the earth to call his own. Soothing him, his father predicted that this boy would succeed to all the dominions that were William's and would surpass his brothers in power and wealth. William knew his sons. Robert and William Rufus died as shiftlessly as they had lived. Not the canny Henry was King of England and Lord of half of France before he finished.

William grew no better. The blow from the saddle while it did not rupture the distended sac of one or another of his chronic diverticula evidently caused such injury to the walls that it slowly necrosed. He must have become more and more toxic and the sac more and more inflamed until during the night of the 8 to 9th of September it ruptured at last, and peritonitis intervened.

The end came in the early morning of September 9, 1087. William who for 4 weeks, had rent the air with groans and torn the bed with writhings had spent the previous night in quiet undisturbed slumber. As the sun rose he woke to the sound of bells and in a weak voice asked what they might be. He had become disoriented for they were the same bells he had heard all the weeks that he lay there the bells of the Cathedral of St. Mary in Rouen routinely tolling for primes. William made one more impassioned well-turned speech commending himself and his soul to God the Virgin and Jesus Christ and with dramatic perfection raised his hands to heaven and drew his last breath with his last well chosen word.¹

Hardly had his chest stopped heaving than a great metamorphosis overcame the pious atmosphere of the bed chamber. His devoted watchers picked up their voluminous skirts and vanished all on the same mission. They ran toward their bequests. The body servants stripped the body, searched the room, turned out the bed, and fled leaving the unlamented Duke lying naked on the floor. Henry not too indifferent to his 5,000 pounds, was already on his way to where his money was to be found. Not until 3 hours later

¹Denique quinto idus Septembris, feria vi, Jam Phoebus per orbem spectantis clara radiorum spicula, euctus ex eorum majoris signi auditu in metropolitana basilica. REVIEWS OF NEW BOOKS

THE book on *Preoperative and Postoperative Care* written by William J. Tourish and Frederick B. Wagner, Jr. presents the routine and methods used by these men in their surgical practices.

It is very well prepared and will be found an invaluable aid to internes and residents. The procedures given are those followed by the authors but they wisely point out the necessity of being alert for other methods which are equally good and which when found useful should be accepted. While routines are necessary and useful, their maximum benefit is achieved only when each patient is treated as an individual problem, and such changes made as may be necessary for intelligent application of the routines in each specific instance. It has additional merit in that it gives detailed specific measures of examination and all phases of treatment.

The constant observation and treatment both before and after operation are stressed. In difficult and controversial cases the importance of seeking the opinions and advice from an internist and from specialists in other fields is emphasized.

The first two chapters deal with the general preoperative and postoperative care. Chapter III describes the management of specific groups of surgical problems. Chapter V deals with the care of the urological patient, Chapter VI with the neurosurgical patient and the final chapter, Chapter VII, which is very well written, deals with the gynecological patient.

This book will serve as a guide to detailed methods and procedures against which the interne or resident may check his own efforts and add those things which are necessary. R. T. BOTH.

THE monograph *Aspetti di patologia placentare* by Massimo Macciotta presents a very detailed and extremely interesting description of the changes found in the placenta in various diseases of the mother. The diseases considered are the pathological conditions of the kidney due to pregnancy eclampsia, nephritis, syphilis, tuberculosis, infectious diseases, malaria, intrauterine death of the fetus and heart diseases.

In addition to the macroscopic findings, such as hypertrophy of the placenta, variations in consistency, color and weight, and particularly variations in the proportionate weight of fetus and placenta, the microscopic findings are discussed in

PREOPERATIVE AND POSTOPERATIVE CARE. By William J. Tourish, M.D., F.A.C.S. and Frederick B. Wagner, Jr., M.D. Foreword by Thomas A. Shallow, M.D. Philadelphia: F. A. Davis Co. 947.

ASPETTI DI ATOLOGIA PLACENTARE. (Pathology of the placenta.) By Massimo Macciotta. Bologna: Nicola Zanichelli Editore. 947.

cluding the finding of Langhans cells, regressive and proliferative changes in the vessels, various regressive changes in the stroma, the red and white nodules so frequently seen and hemorrhagic foci. The article is profusely illustrated with photomicrographs of the findings, and tables are given showing the percentages of the individual findings in the various diseases.

While there are certain findings which are characteristic, such as the destruction of the amniotic epithelium which is seen almost exclusively in maceration of the fetus, the hypertrophy of the villi and the eccentric endarteritis obliterans of the vessels of the villi, so frequent in syphilis, and the finding of parasites in the red blood cells in 70 per cent of the cases of malaria, there is no picture that is absolutely pathognomonic of any of the diseases in question. But if the different pathological findings are checked with a table of the frequency of their appearance in the different diseases, valuable indications as to diagnosis are given. The monograph is worthy of careful study. AUDREY G. MORAN.

THE second volume in the series of textbooks which is being published under the general heading of *The Rehabilitation of the Injured* has recently appeared. It deals with specific remedial exercises and is not concerned with general exercises, games, and recreational activities which will be included later in a volume on recreational therapy. Passive therapy has not been included as its use in the treatment of traumatic conditions has been described fully in many of the standard textbooks on physical medicine.

Watson Jones in his foreword brings out several good points. The death knell of massage has been sounded. No longer must the patient be lulled to sleep with soothing massage; he must be galvanised into activity by invigorating exercise.

Rehabilitation of the injured begins with surgical and manipulative treatment, which is accompanied and followed by physiotherapy, exercise therapy, occupational therapy and recreational therapy and is completed by retraining and resettlement. The process is involved and prolonged. But two principles may be recognised. The first was known to Galen hundreds of years ago. Confidence and hope do more good than physic; he cures most in whom most are confident. The patient must be encouraged; he must be stimulated; he must be inspired; he must learn that success depends upon his effort alone. But the second principle is equally important. Rehabilitation calls not only for recreation; it calls for work and very hard work.

THE REHABILITATION OF THE INJURED. Vol. Remedial Gymnastics. By John H. C. Colson. Foreword by Sir Rossini Watson-Jones, B.Sc., M.Ch. Orth., F.R.C.S. London: Cassell & Co., Ltd. 947.

The literature of rehabilitation is of two kinds: generalizations and the much more rare utterances of those who know how to do the job and who have the gift of imparting the knowledge to others. The author Mr. Colson is among the latter. This book cannot fail to interest medical men, particularly surgeons and physical medicine specialists. It will be of particular value to physiotherapists whose work is to apply and elaborate the principles underlying exercise therapy.

JOHN S. COVATTA.

THE recent book by Hans May has been called quite appropriately *Reconstructive and Reparative Surgery* since it emphasizes the correction of anatomic defects in all fields of surgery. The basic concept of the book, whether dealing with general principles, with anatomic regions, or with specific problems of repair is that there are but a few fundamentals underlying all surgery. These fundamentals do not change with the particular field of the individual surgeon but are the same whether dealing with the head and neck, the trunk, or the extremities. One is not surprised therefore to find described operative procedures for repair of nonunion of the long bones next to discussion of arterial repair and obliterative aneurysms. Nor should the surgeon be startled to find in what is ostensibly a book on plastic surgery discussion of the repair of incisional abdominal hernia, and anal sphincter defects alongside excellent descriptions of correction of lip and nasal defects, deformities of the ears, eyelids and orbits.

Barrett Brown in his introduction to the volume states that "actual procedures are relatively few and they may be carried from field to field. Actually the principles of plastic surgery are the principles of good surgery whether we deal with general surgery or orthopedics or ophthalmology. To many surgeons it has seemed that the application to surgery in general of certain principles so essential to good results in plastic surgery has been one of the factors which has made for real advancement in the science. It is therefore quite fitting that this book embraces so many of the surgical specialties."

The volume falls into three major parts although the author has made five divisions. The first part deals with the general principles of reconstructive surgery starting with a discussion of preparation of the patient, instrumentarium and the various procedures and techniques common to all types of plastic surgery, and includes chapters on wound healing and the treatment of wounds and burns. The second part of the book, divided into three divisions by Dr. May, covers the plastic and reparative surgery of the various anatomic areas—head and neck, the trunk and the extremities. The third part of the book is devoted to illustrated reports of 135 cases, each carefully chosen to bring out some particular operative procedure or problem.

The volume is most generously illustrated throughout the text by many drawings, photographs and

diagrams of operative procedures. In looking at the excellent illustrations and photographs and reading the text pertaining to them one realizes that they represent the actual experience and considered judgment of the author.

The book contains much of interest to every surgeon. Its range of practical applicability is wide. It should be a welcome addition to that section of a surgeon's library where the volumes are well thumbed since often consulted.

MICHAEL L. MARY.

IN nine hundred odd pages, accompanied by 14 illustrations the author of *Surgery of the Incurable Patient* has completely covered the subject including much material on the diagnosis of conditions requiring hospital care. Despite the fact that division of surgery arbitrarily into ambulatory and hospital practice is an artificial one, this volume is needed for an authoritative reference on either procedure. The decision as to whether a surgeon will treat a patient with a given lesion in a hospital or office will usually depend on the facilities available locally and thus must be made by each surgeon individually. Many of the patients described in this volume are ordinarily considered as hospital cases; surgeons who have sufficient hospital facilities will find this volume valuable.

A comparison of this volume with the first edition shows that the sections on infection have been rewritten to include the use of penicillin, which was available at the time the first edition was published. The section on second degree burns has been completely rewritten, the author now advising several different premature dressings in the treatment. A new section on the truss treatment of inguinal hernia has been added. Considerable new material has been added to the chapter on the back, including a consideration of the herniation of the nucleus pulposus. The treatment of gonorrhea has been rewritten to include the use of penicillin. A new section has been added on tendon suture as well as new illustrations for this section. In addition to the specific lesions mentioned a large number of new references have been added to the previous volume. Some new illustrations have replaced older ones. Enough old material was deleted to prevent any increase in the size of the book. A table of contents and an adequately revised index are included.

THOMAS C. DORRANCE.

A very comprehensive, carefully compiled treatise on *Trichomonas vaginalis* and *Trichomonas* by Ray E. Trussell is presented as a foundation for a constructive study of a perplexing clinical problem. Despite the wealth of literature which has accumulated since Doane first described the organism suggested its clinical importance more than two years ago, many features of human trichomoniasis

SURGERY OF THE AMBULATORY PATIENT, by L. E. Brown, M.D., F.A.C.S., ed. ed. Philadelphia: J. B. Lippincott, 1947.

TRICHOMONAS VAGINALIS AND TRICHOMONAS, by Ray E. Trussell, M.D. With an introduction by E. D. Allen, M.D. Springfield, Illinois: Charles C. Thomas, 1947.

remain almost as obscure as when Hoehne revived interest in the problem in 1916. As the author states in the preface, — the time has come to replace the older investigative technic with the modern physiologic approach. This book provides invaluable reference material for any new approach and as such will be welcomed by research workers as well as by gynecologists and urologists who seek a comprehensive, unbiased treatise on the subject.

The work is divided into three parts. Part I "Trichomonas Vaginalis," deals with the morphological, biological and epidemiological characteristics of the organism. Criteria are given for differentiating trichomonas vaginalis from the morphologically similar but separate species which infect the mouth and the intestinal tract. The taxonomic relationship of trichomonas to other protozoa is explained fully in Appendix A and the complete parasite host list of trichomonads (with original reference to each named species) is given in Appendix B. This material will interest the research worker and parasitologist. Part II, Trichomonas Vaginalis Infections, presents in detail the clinical aspects of the disease in women as well as men. Part III, Treatment, outlines the methods which have been employed in the treatment of human trichomoniasis and lists alphabetically the more than 150 chemicals utilized in efforts to eradicate the parasite giving the results reported for each. An imposing list of 1386 references in the bibliography is proof of the zeal with which the author has undertaken the study. To quote again from the preface: "this volume makes the errors and successes of the past readily available for those who would pursue the problem." HAROLD C. MACK

IN the words of the authors of *Essentials of Pharmacology*¹ "This book is intended to serve as an introductory text in pharmacology. On the other hand the general principles of pharmacology have been stressed wherever possible and efforts have been made to indicate what appear to be the coming trends in the field.

This book is a clear and concise coverage of a very extensive field. It is up to date and mentions most of the drugs developed in recent years. Information is to be found here on such drugs as myxanecan, mesantol, tridione, amldone, dibenamine, disopropyl fluorophosphate, antergan, neoantergan, diphenhydramine, triphenylamine, pteroyl glutamic acid, the nitrogen mustards, British antilewisite, chloroquine, paludrine and pentamidine. In addition some of the older drugs such as urethane, which have been put to new usage, are discussed.

Although no claim is made for this book as an investigator's handbook, still a fairly extensive and pertinent bibliography is included at the end of each section.

Because of its brevity (413 pages) and easy reading style it would seem that this book would serve

ESSENTIALS OF PHARMACOLOGY. By FRANK K. Oldham, M.Sc., Ph.D., F. E. Kelsey Ph.D. and E. M. K. Gellink, Ph.D. M.D. Philadelphia, London, Montreal J. B. Lippincott Co., 947

admirably as a 'refresher' source for the busy practitioner and also as a text for medical students and nurses. CARL A. DRAOSTZDT

IN a well organized and comprehensive monograph² I. Karner and Koletsky have presented the currently accepted teachings concerning the calcific changes which occur in the aortic valve.

By a selective use of the literature and with the addition of 200 of their own cases (only those with autopsies are included) they have arrived at their opinions. The statistical data have been analyzed properly and corrected for factors of error.

As would be expected the stress is on the pathologic changes (macroscopic and microscopic). There are listed the morphologic alterations seen grossly and on histologic study. There is one chapter devoted to the clinical considerations however.

Excellent photographs, photomicrographs, and tables are included.

There is a satisfactory concise historical review which actually indicates the reason for the publication.

They conclude that (1) calcific disease of the aortic valve is largely the result of previous inflammation (principally rheumatic) (2) the entity is most common in white males of the older age groups (3) enlargement (by weight) of the heart occurs in three-fourths of the cases, (4) the electrocardiograms vary widely but are in accord with physical laws and (5) there is only a small factor of error in the x-ray diagnosis of calcification in the aortic region.

This volume is of major interest to internists and pathologists is of value to any physician and surgeon, and should be readily available as a reference to all persons in the field of medicine.

M. C. WHEELLOCK.

THE new *Textbook of the Nervous System*³ by H. Chandler Elliott is designed for medical students and anyone beginning study of the human nervous system from a clinical standpoint. The author realizing the student's necessity for knowing something about the nervous system before studying it in detail presents the story twice. The first 95 pages consist of an abbreviated description of the nervous system's form and function, with numerous simple diagrams for illustration which incidentally throughout the book give the story in themselves. After such a short cut the entire nervous system is considered in the second part more completely and technically.

Here again the author does not use a conventional method of anatomical description but presents as far as possible a functional discussion of the parts of the nervous system in logical sequence combining and

¹"CALCIFIC DISEASE OF THE AORTIC VALVE: A COMPREHENSIVE ANALYTIC SURVEY OF CALCIFIC SCLEROSIS. By Howard T. Karner, M.D. and Simon Koletsky, M.D. Philadelphia, London, Montreal J. B. Lippincott Co., 947.

²"TEXTBOOK OF THE NERVOUS SYSTEM: A FOUNDATION FOR CLINICAL NEUROLOGY. By H. Chandler Elliott, M.A., Ph.D. Philadelphia, London, Montreal J. B. Lippincott Co., 947.

tomical description and analogies and diagrams to aid in the interpretation of the physiology.

The sequence of presentation is from the neuron and its parts through spinal cord and brain stem to the larger gray masses, the autonomic system being presented after consideration of the suprasegmental structures. Considerable space is properly given to functional systems in which there is clinical interest as the auditory, vestibular and gustatory systems and the visual system. A brief appendix lists the meanings of most neurological terms, and a working bibliography is included. An atlas of photographs of actual dissections and stained sections of brains completes the book.

The author's wish to avoid unnecessary anatomical detail has led to the illustrations possessing but

few labels, and the structures he wishes to highlight are thus emphasized, as well as by the simplicity of design of many diagrams. A question might be raised as to whether or not there are enough labels and non-diagrammatic illustrations for the beginning student.

The style is lucid and at times pleasantly repetitive in the use of illustrative analogies. Because of his wish to have the student get a clear working knowledge of the basic brain one can sympathize with if not entirely condone, the author's tendency to grasp firmly one horn of certain dilemmas, while somewhat dogmatic in disputed areas. But references to recent literature are generously given in the text to give authority for statements and encourage reading further.

COLLECTIVE REVIEW

CARE OF PATIENTS WITH SURGICAL DISTAL
OF THE CHILI

GEORGE R. MINOR, M.D., Ann Arbor, Michigan

There are many nonoperative considerations in the surgery of the thorax which can be neglected only at the cost of a high mortality as well as a high morbidity regardless of the surgeon's technical skill. In recent years important advances have been made in the preparation and after care of the patient. This presentation is a review and evaluation of these agencies. No reference will be made to diagnostic, operative or anesthetic procedures that involve the patient's preoperative or nonoperative treatment.

DISONANTIVE RELAXATION

Feeding and depletion. The preparation of a patient begins when it becomes apparent that he may be a candidate for operation. Any patient who has a malignant neoplasm or a chronic infection may be assumed to have an anemia. As a part of the history, a few pertinent questions relative to dietary habits and food intake can aid in the estimation of degree of subnormal hemoglobin. The obese person should be told that an additional weight is necessary before operation and the thorax can be undertaken with maximum safety. Conversely, such a patient may be hospitalized, and to the person between the two extremes, a still calmer method of treatment, at days or weeks later. In fact, the employment of these means are again a

dietary instructions should be begun at once if there is any indication for their need.

In some diseases there is an optimum time for operation. The wise surgeon, for example, will rarely perform a major operation on a tuberculous patient who has not been under medical observation for at least 6 months. He will be careful to carry out resection for bronchiectasis during a remission when pneumonia and hilar adenopathy are likely to be at a minimum (6). Since the intrabronchial instillation of a fixed oil occasionally produces a fulminating reaction, it is a wise precaution to give a prophylactic pneumonia attack by the oral route a few weeks after the making of a bronchogram (6).

From the work of Blalock, I have read that Elman and others (as) still were skeptical as to much depend on the care without hospitalization prepared for operation. Against this I have written, and I believe I have been able to convince them that the best results are achieved by the use of the hospital. I have also written that the best results are achieved by the use of the hospital. I have also written that the best results are achieved by the use of the hospital.

tion (33) An elderly patient with a history suggesting coronary disease may tolerate the operative procedure of pneumonectomy but he is more apt to develop coronary insufficiency in the first few postoperative days than is the patient with normal coronary arteries, especially if any degree of shock or anoxia should occur during the operation. The diagnosis of congenital cardiac lesions, the preparation for operation of the patient with constrictive pericarditis, and the management of cardiac and renal complications require the close co-operation of the internist. Digitalis, in the absence of congestive failure, is not only unnecessary but probably harmful (38) Patients in whom the cardiovascular tone is poor after months of complete bed rest tolerate major surgery better if they are allowed to sit and walk for from 5 to 20 minutes twice daily for at least a week before operation.

Respiratory function is of great importance in thoracic surgery. Vital capacity is still commonly measured preoperatively but since it represents only one component of the ventilatory function and is subject to so many variables it is useful only in the broadest sense (4) In young patients lobectomy is usually followed by little appreciable reduction of the respiratory reserve. Indeed, the disease itself is more dangerous than operation or the possible loss of a little respiratory reserve. In the older patient who has a bronchial or pulmonary neoplasm the prognosis is so poor if resection is not done that considerable leeway in the matter of functional risk should be assumed. A rough clinical estimate of respiratory function can be arrived at by the correlation of roentgenographic findings with the efficiency of diaphragm and rib movements, studied fluoroscopically. In the roentgenogram, evidence of pleural damage, widespread nodular lesions, and emphysema are of considerable significance. At the fluoroscopic examination, if the free excursion of the diaphragm is limited for any reason, there is undoubtedly a decrease in its ventilatory power and consequently in the respiratory function. The response of pulse and respirations to the performance of some simple task, such as climbing a flight of stairs, has great practical application but alone cannot, of course, be expected to gauge respiratory function.

Spirometric and bronchospirometric determinations, however, are often of great assistance in the detection of the degree of functional impairment produced by discrete nodular scars or other pulmonary infiltrations, emphysema, pleural adhesions and previous collapse therapy (28) Recent observations by Levy, Seabury and Hull

indicate that there are often remarkable discrepancies between the respiratory function (ventilatory and respiratory components) as estimated from data on patients' records, and that revealed by laboratory determinations. They conclude

Without bronchspirometric studies one cannot properly appraise the percentage distribution of pulmonary function even when the complete clinical picture, radiological data, and vital capacity are taken into consideration. Information, not otherwise obtainable, is gained with sufficient frequency to justify the expense, time, and risks entailed.

Prophylaxis One of the more important aims of preoperative preparation is the elimination of sources of infection in the upper as well as the lower respiratory tract. The grosser aspects of oral sepsis should be remedied by a dentist before any intrathoracic operation. Major surgery of the paranasal sinuses, however, is of more lasting benefit if it is postponed until at least several months after the elimination of suppurative pulmonary disease (47-76)

In any disease characterized by pulmonary suppuration postural drainage is a fundamental treatment even when operation is not possible. It is essential for preoperative preparation and if the best results are to be obtained it must be used thoroughly and frequently. Its effects may be greatly enhanced by one or more painstaking bronchoscopic aspirations. On the morning of operation tuberculous as well as nontuberculous patients should have a thorough postural drainage. The inhalation of steam is often a valuable adjunct to posture. Beecher feels that postural drainage should not be done within 2 hours of operation because the patient's continued coughing may hinder induction of anesthesia (15) Bronchoscopic aspiration is usually not done on the morning of operation. Nevertheless, this may be advisable if the effort required to raise large amounts of sputum is tiring to the patient or if after postural drainage his cough and respirations continue to sound moist.

In many patients with bronchiectasis the administration of penicillin produces marked change in the sputum. The bronchopulmonary secretions decrease in amount, become less purulent and often lose their offensive odor. Occasionally when gram positive cocci predominate the sputum practically ceases after 4 or 5 days of penicillin therapy (68-69-81-50) Penicillin alone has certain inadequacies. It has no significant effect on most gram negative bacilli and with the disappearance of the cocci from the sputum the bacilli appear or increase in number (50-81) These organisms have been found to grow luxuri-

the procedure. Tuberculosis, for instance, may not be suspected, but a series of examinations of the sputum concentrate should be done routinely. From time to time the unexpected finding of acid fast bacilli clarifies a doubtful diagnosis or demonstrates that tuberculosis coexists with some other pulmonary lesion. This discovery except in the presence of a neoplasm, would be very likely to affect the decision in regard to treatment. Whatever the etiology of the disease may be, if the patient raises sputum, its daily amount should be recorded, preferably in grams, for serial comparison.

In addition to routine blood and urine examinations, determination of the type and Rh factor of the blood must be done. Abbott (12) has emphasized the fact that the concentrations of the constituents of the blood show a surprising variability which depends on the plasma volume. The proteins of the plasma roughly mirror the state of the other body proteins in the proportion of about 1 to 30 (36) but in states of chronic malnutrition (as in a patient with esophageal obstruction), when body proteins are diminished the blood volume itself is often reduced (37)—perhaps in an attempt to retain a favorable concentration of plasma protein. A severe anemia may also be present, but due to the masking effect of a decreased plasma volume, the protein concentration, red cell count, hemoglobin, and hematocrit may all deceptively appear to be normal. A simple means of ascertaining plasma volume would doubtless become a great asset. Obviously no single test is absolutely trustworthy when it is considered apart from others or without regard to the history and clinical appearance of the patient (12).

When the patient is admitted, he should be given a high protein, high carbohydrate diet. If depletion is severe, as it is apt to be in carcinoma of the esophagus, some days or weeks may be necessary to overcome it sufficiently to make operation reasonably safe. Varco has demonstrated that anyone who can take fluids orally can ingest more than 8,000 calories per day without discomfort (91). He feels that patients should be carefully prepared for from 5 to 7 days for each 10 per cent of body weight which they have lost. For those who are completely obstructed intravenous feedings are advisable although the intake of both glucose and protein hydrolyzate may be limited by the amount of fluid which can be administered safely. In such cases the advisability of a jejunostomy or gastrostomy should be considered (85).

Not only the blood volume but the red cell mass has a relation to the early onset of surgical

shock (37). A deficiency of the latter can be corrected only by transfusions of whole blood. Early correction of a severe or prolonged anemia may result in a feeling of security which is not justified. Not only has the circulatory system become accommodated to the decreased volume but the heart may have suffered some damage. To increase the blood volume rapidly imposes new work on the injured myocardium before it has had an opportunity to recuperate. Large transfusions given frequently are apt to produce pulmonary edema or cardiac failure. Small transfusions every 1 to 3 days over a period of 1 to 3 weeks, if necessary, are probably safer. While it is possible and sometimes necessary, to give a low type O blood to a patient of another type, it is obviously better to use only homologous blood. If negative blood may be given safely to Rh positive persons, but the reverse may not be undertaken without the risk of stimulating the production of an anti-Rh agglutinin in the blood of the recipient (68).

The need for adequate reserves of ascorbic acid for satisfactory wound healing is well known (5, 59, 62, 98, 97). The debility of a wound following pulmonary resection, or the opening of a bronchial stump or an esophageal anastomosis is a catastrophe which may be fatal. The bone, blood, and urine levels of ascorbic acid are disturbed by anesthesia (17) and operation. Injured tissue immediately demands large amounts of ascorbic acid (97) and, if the reserves are low, the remainder of the body is depleted in the absence of adequate intake. Lund (61) has found that a daily intake of 2 grams is necessary to maintain a relatively normal blood level in some extremely burned patients. In general, it is not necessary to carry out elaborate saturation tests. It is simply to assume that the average patient is deficient and to give him at least 1 gram (98) per day for several days before operation. With regard to the other vitamins, it has been recently suggested (59) that the severely ill surgical patient may need more of these substances than was previously supposed (51). Levinson *et al.* recommended, in addition to 1 gram of ascorbic acid, 50 milligrams of thiamin, 50 milligrams of riboflavin, and 500 milligrams of nicotinic acid daily for several days before and after operation.

The surgeon usually relies on the interest in doubtful cases to estimate the status of the heart and kidneys. In young persons, well compensated valvular lesions do not add greatly to the operative risk (38). Congestive failure, coronary disease, and syphilitic aortitis, however, create a considerable hazard to the performance of any opera-

necessity for such co-operation as he may be able to give postoperatively he is ready for operation

CARE OF THE PATIENT DURING OPERATION

The proper management of a surgical patient is the continuous application of functional principles this is particularly important during the relatively brief period of the operation, when new and powerful factors are being introduced. The immediate preoperative routine need not differ from that generally used before any major operation under inhalation anesthesia. A mild sedative is usually given the night before operation and often repeated in the morning except for this, nothing should be given by mouth after midnight. Reference has already been made to the preoperative evacuation of pulmonary secretions. Operations which can be performed under local anesthesia e.g., minor procedures for tuberculosis or the drainage of empyema and lung abscess, require in addition only codeine or morphine as premedication. Either ether or cyclopropane, in closed circuit, is used successfully in thoracic surgery. Each has certain disadvantages which its proponents are inclined to minimize. More important considerations than the agent itself are (1) a smooth induction (2) an adequate airway with a high proportion of oxygen in the mixture of anesthesia gases (3) a moderately deep plane, with attention on the part of the anesthetist to dangerous reflexes which may be produced by the surgeon and (4) the scrupulous cleansing of the tracheobronchial tree as soon as moisture is detected.

The use of an intratracheal tube is rarely necessary for thoracoplasty but a tube should be employed in any major intrathoracic operation when the patient is more than 10 years of age. At the University of Michigan Hospital it is seldom used in younger or undersized children because of their increased liability to laryngeal edema, although in some clinics tracheal intubation is practiced almost routinely in children of any age, for any thoracic operation. No rigid rule however can be adopted since circumstances may be such that the acceptance of the possibility of laryngeal edema and the performance of an immediate tracheotomy may be preferable to omission of the tube. The presence of such a tube affords the anesthetist complete control of the anesthesia and the respirations, even in the event of a bilateral pneumothorax it prevents the interference of adducted vocal cords with respiratory exchange and gives ready access to potentially dangerous bronchopulmonary secretions. While an inflatable cuff makes the system absolutely gas

tight it has the disadvantage of being relatively difficult to insert and occasionally is responsible for serious and even fatal complications. If the proper size of Magill tube is chosen, the anesthetist will have little difficulty with leakage. The latter can be controlled, if necessary by the use of a face mask over the patient's nose and mouth, and the open end of the intratracheal tube, or by a pharyngeal pack. In adults the tube is more easily inserted under local than under general anesthesia. The pharynx larynx and trachea are prepared as for bronchoscopy while the patient sits upright on the side of the table. The lubricated tube is then passed with the aid of a metal stylette and a laryngeal mirror after which the patient is placed in the supine position and the tube is immediately connected with the machine and strapped in place with adhesive. The person who passes the tube should ascertain from its length how far it must be inserted so that the end will lie not less than 2 centimeters above the main canna, the position of which is marked externally by the second costal cartilage. Maier (65) warns against the use of too small a catheter for aspiration through the intratracheal tube. One that may be adequate for the removal of thin secretions may not be large enough to aspirate the thicker material expressed by the collapse or manipulation of diseased pulmonary tissue. A number 16 F catheter with its end cut off squarely or obliquely should be adequate for use within a large Magill tube, but smaller sizes of the latter necessitate correspondingly smaller aspiration catheters. After the induction the patient is placed in position and securely braced and strapped. If the thoracoplasty position is used the dependent leg is flexed the weight of the uppermost leg which remains straight, can be supported by a pad so that it will not interfere with the flow of fluids into the opposite long saphenous vein at the ankle. A cannula or large needle is inserted into the saphenous vein and the administration of a solution of 5 per cent glucose begun at once. The peripheral veins may be so contracted in shock that fluids will not flow by gravity. Since it is usually necessary at such times to give blood rapidly in large amounts a three way stopcock and a 20 or 50 cubic centimeter Luer syringe should be available to insert into this system. The table should be tipped until the patient is in a 15 degree Trendelenburg position.

It is of great importance for the surgeon and the anesthetist to understand one another's difficulties (65). On the one hand the surgeon's patience during induction or his failure to pause should the plane of anesthesia become too shallow

cubic centimeters of blood mixed with the same amount of saline solution carries into the vascular system almost 30 grams of sodium chloride (82). It is especially important to dilute blood given to infants with as little saline solution as possible, since many become edematous when the operation precludes feeding for the first few days after operation. On the whole, in view of the fact that there is no need for the extra sodium, it is probably better not to use isotonic saline solution, even though it is the most satisfactory diluent for blood.

It is very difficult to estimate blood loss clinically. Indeed shock may occur before the surgeon realizes the magnitude of the loss. Wangenstein (93, 14) has developed a simple gravimetric method by which blood loss is serially determined throughout the operation. Only dry gauze sponges or packs of standard weight are used to remove blood from the operative field. These are carefully collected as they are used and are weighed at frequent intervals on a balance accurate to 1 gram. Each gram gained by the sponges is assumed to represent 1 cubic centimeter of blood. Since the specific gravity of blood is greater than 1, the calculation is not strictly accurate but the error is negligible and is more than compensated for by the inclusion of fluids from serous membranes. In fact the authors suggest the subtraction of 10 per cent to correct for such fluids. While this method is obviously not exact it seems to be of considerable practical value in that it gives a better continuous estimate than has ever been available before. The operative field can be washed with cleansing or antiseptic fluids after the free blood and clots have been removed for weighing. Warm moist packs, with any blood they contain are simply not weighed.

When that part of the operation associated with bleeding has been completed and the necessary blood has been given, a 5 per cent solution of glucose may then be given. This should not be allowed to flow rapidly since the lowering of the plasma protein concentration which occurs when fluids are rapidly administered intravenously predisposes toward pulmonary edema by lowering the colloid osmotic pressure of the blood as well as by increasing the blood volume (40). This is particularly important during and after pneumonectomy when the entire cardiac output must suddenly be forced through the vascular bed of the remaining lung. Altshuler *et al* have shown that the total capacity and its components are slightly reduced (9.6 per cent) even in normal persons, large infusions given intravenously at rates of more than 30 drops per minute. The pulmonary villary bed is voluminous and can accommodate

considerable overdilatation at some cost to the intra-alveolar space. However patients with pulmonary disease who are undergoing drastic reduction of pulmonary tissue by resection or collapse, under an inhalation anesthetic, should not be subjected to even the slightest avoidable increase in the distention of this elastic system. When its capacity is finally exceeded and the hydrostatic pressure in the pulmonary capillaries surpasses the colloid osmotic pressure of the plasma, pulmonary edema occurs suddenly. Cournaud and Berry (27) state that the most important cause of early death following pneumonectomy is the failure of proper hemodynamic adjustment to take place. Strains produced by dilution of the blood and overfilling of the vascular system, caused either by rapidly given infusions or by gross overtransfusion within a short period (39) may prevent this adjustment. The slow intravenous flow of glucose solution may be allowed to continue for several hours after operation until a total of from 3,000 to 5,000 cubic centimeters of fluid, not including blood has been given. As has been intimated the use of isotonic saline solution beyond the optional amount for dilution of blood is inadvisable in view of the decreased postoperative excretion of sodium by the kidneys.

The usefulness of penicillin in the pleural space has been amply demonstrated (3, 74, 90, 94, 96). The ability of this drug occasionally to sterilize even an established empyema, which is caused by penicillin sensitive organisms, can no longer be doubted. Since pleural complications following open chest operations are with few exceptions, due to gram positive cocci, there is considerable reason for and none against, its routine use in large amounts whenever the pleura is opened. From 200,000 to 400,000 units in distilled water can be left in the pleural space or injected after the aspiration of the residual air through a catheter left in the wound for that purpose during its closure.

Most surgeons do not drain the pleural space after pneumonectomy preferring rather to retain the fluid (which later becomes an organized exudate) as a space filling medium and to adjust the mediastinal position by thoracentesis. This also has the advantages of allowing high concentrations of penicillin and of avoiding the introduction of bacteria by way of a drain. After lobectomy early expansion of the remaining lobe to cover the hilum of the resected lobe and to obliterate the empty part of the pleural space as soon as possible is desired. Because of the danger of contamination and the obvious difficulties of thor

for certain manipulations, is dangerous. On the other hand, the anesthetist's unfamiliarity with the mechanics and procedure of the operation, failure to keep the airway free of secretions, to prevent anoxia, and to discuss with the surgeon the patient's condition or details of blood loss and fluid replacement can be even more disastrous. At 20 or 30 minute intervals, at phases of the operation when temporary interruption is feasible, and only after aspiration if there is any hint of moisture, the pressure in the anesthesia system should be increased by the gradual application of positive pressure until the lungs are moderately inflated, the mediastinum thus being returned toward its normal position (15). This pressure should not exceed from 10 (65) to 15 (55) centimeters of water. If the system has no manometer the anesthetist must be guided by instructions from the surgeon, who has the lung under his direct observation. Once the desired degree of moderate inflation is attained it should be very gradually released (15). Manual pressure on the breathing bag is usually not only unnecessary but inadvisable since dangerously high intrabronchial pressures, the effects of which are well known, can be unintentionally produced (5).

Vagal reflexes can often be prevented or abolished by the injection of the vagus nerve with procaine solution or by dividing it below the origin of its recurrent laryngeal branch. Injection of the peribronchial tissues may prevent afferent impulses produced by manipulation in this region. Even though peribronchial injection may not be deemed necessary for this purpose (18) it produces no damage and may be of assistance as a mechanical aid to dissection by distending the tissues.

Distortion of the mediastinum such as occurs when the lung or a mediastinal tumor is being pulled upon is well known to produce lowering of the blood pressure by mechanical or reflex action (18). When this occurs it is important to interrupt the traction temporarily. The motion of the diaphragm can be stilled by injection or crushing of the phrenic nerve. This has been objected to on the grounds that an active diaphragm is of importance in aiding the postoperative expansion of the upper lobe following lower lobe lobectomy (47-55). Most surgeons believe that a temporary paralysis, produced by crushing the nerve at operation or within the first postoperative week, is desirable to assist in the obliteration of the space left by lower lobe lobectomy. Paralysis of the diaphragm during pneumonectomy may make the operation easier and reduce the volume of the space to be filled postoperatively the paradoxical

motion which ensues, however transient, from the air or fluid of the closed space a protruding movement to a labile mediastinum which may be harmful (53).

Except for the prevention of anoxia, which is of more immediate importance in the open care of the patient than blood loss and its replacement. It is obvious that any consideration of blood loss is meaningless unless size (body weight) is taken into account (26). For example, a loss of 200 cubic centimeters amounts to 2.4 per cent of the total blood volume of the average sized adult. This is relatively trivial, whereas in a 40 pound child 200 cubic centimeters is 10 per cent of the blood volume. The amount to replace blood, volume for volume, as it is (26-29-80). It is also important during and immediately after pneumonectomy not to give more blood than has been lost (39). Insofar as this can be determined. Dangerous strains on the body's homeostatic mechanism are thus mitigated, and convalescence will be shortened. White and Linton (95) reported 1,607.5 cubic centimeters as the average blood loss for 10 lobectomies and 1,431 cubic centimeters for 6 pneumonectomies. Sir Baronofsky *et al.* found a total average of 1,200 cubic centimeters for 14 lobectomies and pneumonectomies. An extensive revision or Shiel thoracoplasty can scarcely be performed with a loss of 1,000 cubic centimeters, and may involve much more. The surgeon thus has a fair knowledge of the average loss which he may have should not embark on a major operation when the estimated amount being immediately replaceable. If he proposes to remove a small, atelectatic lobe which has been the seat of bronchiectasis in some years and in which repeated attacks of pneumonitis may have produced dense adhesions, he can expect much greater than the average loss of blood. Since the largest loss usually occurs within the first hour and a half, blood should be started at or even before the time when the decision is made. In the event of unexpected, sudden massive blood loss there is no contradiction to the rapid administration of blood with a syringe and three way stopcock interposed in the intravenous system until restoration of the approximate amount lost has been effected. The lives of many war casualties were undoubtedly saved by large amounts of blood and plasma given by this means.

The viscosity of whole blood may be decreased by dilution with a third, a half, or an equal volume of isotonic saline solution. There is, however, no need for the replacement of sodium, and it should be remembered that the administration of 1,000

removed. In pneumonectomy it is desirable only to prevent displacement of the mediastinum from its position near the midline. The pressure in the air-filled hemithorax should be measured with a pneumothorax apparatus as soon as the patient can be safely placed on his back. If the inspiratory and expiratory pressures vary much from approximately 14 to 0 centimeters of water they should be readjusted by aspiration or injection of the necessary amount of air.

The leveling of the table and movement of the patient onto his back or into his bed tend to redistribute the blood volume. This may temporarily simulate blood loss and impending shock can be precipitated unless changes of position are effected very gradually (15).

The removal of the intratracheal tube should be preceded by thorough aspiration of secretions, first from the oropharyngeal and nasal cavities and then by means of a catheter in the intratracheal tube from the tracheobronchial tree. With few exceptions, however, bronchoscopic aspiration of the bronchial passages should also be done after pulmonary resection and after any operation when the respirations sound wet. Even after the most thorough preliminary aspiration by means of a catheter introduced through the intratracheal tube it is not uncommon to discover shortly afterward, on bronchoscopic visualization, secretions or clots in the lobar orifices of the dependent lung. The effect of such secretions is often demonstrable when films made directly after operation show surprisingly large areas of atelectasis in the lung of the nonoperated side. If bronchoscopic aspiration is to be done the plane of anesthesia should be deepened somewhat before the intratracheal tube is removed, not only for ease in the introduction of the bronchoscope but for safety (16). Death due to cardiac arrest has followed more than once the performance of bronchoscopy in a patient under light general anesthesia (70). Some authors even advocate the intravenous injection of 0.8 milligram of atropine sulfate (grains 1/75) from 10 to 15 minutes beforehand (16) as an added attraction.

A film of the chest made while the patient is still on the table is useful in showing the degree of inflation of the lung and the position of the mediastinum, as a check upon percussion and auscultatory findings. Should decostalization in any operation, for example an anterior thoracoplasty have left an area of thoracic wall without bony support so that respiration or cough produces paradoxical motion the dressing should include sufficient packing and should be applied with sufficient firmness to reduce such motion to

a minimum as well as to increase the desired collapse of the lung or pleural space.

CARE OF THE PATIENT AFTER OPERATION

The postoperative occurrence of anoxia is probably underestimated in thoracic patients because neither dyspnea nor cyanosis is a reliable indication of any but great oxygen want (66, 55). Oxygen should be used after thoracoplasty if the patient has a low respiratory reserve and of course, if cyanosis, shock or tachycardia is present or if the patient exhibits other clinical evidence of anoxia such as headache, restlessness, or confusion. It should be administered to all patients who have had pulmonary resection. The patient who has had a pneumonectomy should be returned to his room breathing oxygen through the mask of the anesthesia machine.

Oxygen equipment should be ready for immediate use in the patient's room. A mask such as the Boothby Lovelace-Bulbunan is rarely necessary and has some disadvantages. A nasal tube also possesses some drawbacks but is a relatively simple device which can be counted on to deliver up to 40 per cent oxygen in the inspired air. The irritating action of the tube can be minimized with an emollient and the dryness of the oxygen must be mitigated by passing it through water. Unnecessarily prolonged use of oxygen is to be avoided (55). It does not relieve all types of dyspnea, it thickens the bronchial secretions by its drying action, it can act as a respiratory irritant (55) and its administration may make adequate care and early mobilization of the patient difficult. The use of oxygen can usually be discontinued safely from 18 to 36 hours after lobectomy but it should be kept at the bedside and used again in the event of any complication. An incompletely expanded lobe is somewhat like an atelectatic lobe; there is a discrepancy between ventilation and circulation, the mixed arterial blood having an oxygen saturation which is lower than normal. Some of the clinical signs of oxygen deficiency have already been mentioned but, according to Maier and Courmand (66) and others (55) the only completely reliable guide to the degree of oxygenation of the blood is the determination of arterial oxygen saturation. The continuance of oxygen therapy for as long as 48 hours, or more, is often advisable after pneumonectomy because of the extensive adjustments needed to re-establish cardiopulmonary balance.

Oxygen is only rarely necessary following such intrathoracic operations as the removal of a mediastinal tumor when the patient has no pulmonary disease provided that operative shock

acutestis most surgeons prefer to drain the space for at least 48 hours. A number 28 F mushroom catheter from which the distal half of the mushroom has been trimmed away to leave a flange is conveniently placed through an intercostal stab wound one or two interspaces below the incision at the posterior axillary line. The catheter ends dependently with the usual water seal. It should be clamped near the chest for at least 4 hours after operation to avoid immediate loss of the penicillin solution. White (94) has suggested an ingenious modification of this standard drainage. An intercostal catheter is clamped and incorporated in the dressing. Each day the accumulated fluid is removed and penicillin injected through the tube with aseptic technique. The catheter is withdrawn between the third and fifth days and further collections of fluid are removed by thoracentesis. Using this method he has had only 2 empyemas after 36 lobectomies, in both of which bronchial fistulas were also present. These occurred after extensive resection which left a large dead space that could not be obliterated because of the limiting adherence of the remaining pulmonary tissue.

Intrathoracic procedures which do not involve the esophagus or the lung are generally followed by closure without drainage. Fluid in varying amounts always accumulates after operation and is easily removed by thoracentesis. The pleural or extrapleural space should be kept as dry as possible. When a pneumonotomy is done for drainage of a tuberculous or other type of abscess, the cavity is snugly packed with narrow gauze which although it is ultimately replaced by a large tube need not be changed for the first 3 postoperative days.

The type of drainage required for empyema depends upon the size of the space and the mobility of the lung and mediastinum. It is safe to assume that most nontuberculous pleural abscesses need drainage by rib resection. A small inelastic space may be handled safely by wide incision and gauze packing. Large spaces, however, should be drained by a large tube ($\frac{1}{2}$ inch inner diameter by $\frac{3}{4}$ inch thickness of wall) of gum rubber. To be airtight the tube must fit snugly in the incision through the deep layer of the pericostum and parietal pleura. Vaseline gauze is usually packed between the tube and the extracostal muscles and the outer end of the tube is closed by a water seal. The tube is fixed in position by adhesive strips passed through a safety pin in its wall at the level of the skin. Johnson (54) has suggested an airtight dressing which is effective even over large openings when suction is to be applied. This con-

sists essentially of a rubber glove from which the fingers have been cut off, and which is split along the ulnar side. The drainage tube is inserted through the tip of the thumb and the resulting large square, trimmed to appropriate size, is applied to the operative defect with waterproof adhesive, the thumb sheathing the tube closely. Water sealed drainage tubes, while not always necessary for safety in limiting the respiratory variations of intrathoracic pressure, encourage expansion of the lung by the negative pressure created within the system by the dependent column of water. In addition, the tube provides a neat mechanism for removing irritating and odorous exudates from the neighborhood of the wound.

The healing of a wound is related not only to the body protein (88, 73) and ascorbic acid reserves (97) but also to certain technical details which are too well recognized to need discussion. In the closure of an open chest, however, there are several points worthy of attention. Johnson (5) has suggested the crushing of several intercostal nerves near the spine, above and below the incision, to minimize postoperative pain. Except its posterior portion the wound should then be anesthetized. Annoying paresthesias and weakness of the upper abdominal muscles anterolaterally for several months after operation occur in the crushing of 4 or 5 intercostal nerves, especially those below the seventh. The nerve corresponding to the incision and the ones immediately above and below it may with advantage be infiltrated with a solution of some local anesthetic just before closure of the wound. Although the effect of this anesthesia is likely to last less than 24 hours, external injections can be repeated at will during the immediate postoperative course.

The incision of the parietal pleura and pericostum, or intercostal muscles, can be closed with or without pericostal sutures. Since an intercostal closure is weaker than a closure utilizing pericostum, the former can be supplemented by a few pericostal sutures placed around adjacent ribs beneath the pericostum (70). A careful closure of the deeper layers may occasionally be followed by massive subcutaneous emphysema (63). Delaying the closure of the thoracic wall the lung or remaining pulmonary tissue should not be fully inflated lest it be torn by the needle. Expansion can be more safely obtained and the amount of air entrapped within the pleural cavity rapidly regulated by the temporary inclusion in the wound of a catheter through which, after approximation of the extracostal muscles, the remaining air can be aspirated following lobectomy and the catheter

and should never be neglected. It must be performed at least once daily however to have much significance. Rales, rhonchi clicks and wheezes are best heard during and immediately after coughing. It is often possible to determine quickly the position of the mediastinum the presence of a pneumothorax or consolidation or the presence or absence of breath sounds or pleural fluid.

The parenteral administration of fluid is seldom important in the thoracic patient after the first 12 to 24 hours, since most patients are able to take fluids orally. A full diet should be resumed as soon as possible. In the average adult who has no renal disease the route of administration and the exact amount of fluid given are of less importance than the maintenance of a minimal daily urinary volume of 1,200 to 1,500 cubic centimeters. Diseased kidneys may require a much larger urinary output to carry off the products of metabolism and the range of sodium adjustment is apt to be considerably narrowed. If the sodium intake is rigidly curtailed fluid in large quantities can usually be given orally without danger.

An operation on the esophagus may occasionally require that nothing be taken by mouth for as long as a week. It is essential in such a case to furnish by the intravenous route not only enough fluid to produce a satisfactory urinary volume but to supply at least 200 grams of glucose daily and as much nitrogen in an assimilable form as possible. Cutting and Cutter have shown that in normal subjects the lapse of only 48 hours without food can produce a lowering of the total circulating plasma protein from 170.7 grams to 156.5 grams (8.3 per cent) even though the concentration may remain unchanged. In addition extensive surgical procedures themselves cause a negative nitrogen balance which may last many days.

It is difficult to realize the overwhelming burden which can be placed for a few days postoperatively upon the body's protein economy by the combined effects of chronic disease incomplete repletion before operation and operative blood loss. To these are often added the results of days of partial starvation and the variable loss of fluid containing both protein and red cells into the pleural space. Unless these effects are partially counteracted convalescence will be hazardous and prolonged. Elman recommends that not a single day be allowed to pass without furnishing glucose with nitrogen in the form of protein hydrolysate. This is a more efficient and economic way of furnishing the raw materials for protein synthesis than the use of plasma. Two liters per day of 5 per cent amigen in 10 per cent glucose solution furnish 100 grams of amino acids, 200 grams of glu-

cose and 5 grams of sodium chloride. Elman stresses the fact that amigen should be handled and given with more care than is customarily accorded to intravenous solutions since it is an ideal culture medium for the growth of bacteria. Even when it is given at speeds of less than 500 cubic centimeters per hour unpleasant reactions may occur unpredictably. One of the offending components is probably glutamic acid (79). The occurrence of any suggestive allergic reaction is regarded as a contraindication to the further use of the protein hydrolysate (36).

The fluid which accumulates in the pleural or wound space postoperatively or which is carried off by a drainage tube or by thoracentesis, is only slightly less rich in protein and often in red cells, than is the blood itself (6). Its loss differs from hemorrhage only in that it occurs over a period of days rather than hours (89). Indeed, it is a sort of slow plasmapheresis with the additional loss of red cells. Since this drainage takes place slowly the body with its various restorative mechanisms is usually able to adjust itself to the loss. But poor wound healing, weakness, and greater liability to infection are likely to occur if it goes unrepaired (52-99). The total average loss of bloody serum in Thornton's series of 12 consecutive lobectomies was found to be 673.3 cubic centimeters. The hemoglobin content of such fluid may be as high as from 6 to 8 grams per cent (87). The concentration of the plasma proteins fell 1 gram per cent between the third and fifth postoperative days (89) with similar decreases in the hematocrit value, hemoglobin level and red cell count. Thomas, Adams, and Thornton studied 19 patients who had had major thoracic operations. The average postoperative lowering of hemoglobin was 2.1 grams per cent, most of which occurred between the third and seventh days. The normal person who suffers an experimental loss of from 15 to 20 per cent of his blood volume, restores his plasma protein concentration to a normal figure within 72 hours because he has adequate reserves of body protein (34). In these 19 patients, however the plasma proteins returned to the preoperative level only after 9 days. At the end of from 7 to 12 days postoperatively the red cell volume was still less than the preoperative value by from 208 to 914 cubic centimeters. The obvious answer to such insidious blood loss is transfusion controlled by accurate determinations of red cells, hemoglobin and hematocrit (87) at 2 day intervals for the first 6 or 8 days after operation.

The status of the lungs, mediastinum and pleural and extrapleural spaces can be followed accurately only by films or by fluoroscopy. If a

did not occur and the lung was completely expanded at the end of the operation. Such a patient does not need the Trendelenburg position as a rule. For unconscious patients, however, who have undergone a long major operation the Trendelenburg position has several advantages. Venous return is encouraged and bronchopulmonary and pharyngeal secretions, as well as vomitus, drain toward the mouth. In addition to having the bed inclined from 10 to 15 degrees, patients who have had a thoracoplasty or intrathoracic operation should be placed on the side which was operated upon and should spend most of their time there except for the periodic changes in position already discussed.

It is essential that a competent nurse be at or near the bedside for the first few postoperative hours. The blood pressure and pulse must be followed closely and the pharynx aspirated when necessary. As soon as the patient is conscious he should be instructed to cough. Manual support in the region of the wound is of great assistance to him at this time. When the blood pressure has become stabilized at a normal level and the patient is fully awake, he is more comfortable lying flat than with his head down. For aid in raising his sputum he may be assisted to a sitting position for a few moments, since patients often seem better able to "reach" their secretions when they are sitting erect than when they are recumbent. The importance of keeping the tracheobronchial tree free of secretions cannot be overemphasized. While the patient should spend most of his time on the side of the operation, at hourly intervals he should be turned on his good side and told to cough, even though his respirations may sound dry. The slightest evidence of bronchial moisture is the signal for an attempt to evacuate the offending secretions.

Carbon dioxide is a liquefying agent which reaches the smaller bronchioles and is of great value in loosening secretions there both by its solvent action and by the hyperventilation it induces. The iodide expectorants and steam apparently produce an increase in the output of respiratory tract fluid (23) but this is said to be largely from the major bronchi rather than from the finer ramifications where the secretions are viscid (48). Holinger recommends the addition of steam when ever oxygen is used in order to counteract its drying antexpectorant effect on the respiratory mucosa (48). A constant temperature bath for oxygen humidifiers would be of considerable advantage if it were available. Certainly of the common expectorants, carbon dioxide and steam are the most useful, the former should always be used to the point of moderate hyperventilation

before the patient coughs, at intervals of not more than 2 hours the first few days after operation.

A considerable proportion of the success in meticulous postoperative care of the patient can be carried out by the surgical staff. If it is known, for instance, that pain makes the patient reluctant with a splinted hemothorax and a suppressive cough (24) moderate doses of a narcotic may enable him to extract the maximum efficiency in his cough by dulling its acute pain factors. For all narcotics depress respiration to some degree they must be used with caution. Morphine is safe in doses of from 8 or 10 milligrams at 4 to 6 intervals is better than larger doses at 4 to 6 periods. If the patient has a marked decrease in respiratory function, demerol or codeine should be employed rather than morphine, for neither is of pain. The injection of several alcohol nerves posteriorly, above and below the incision with a local anesthetic solution may afford lasting relief for an indefinite period and can be repeated when necessary (24). If the sequence of pain-spasm-cough suppression is not broken, the postoperative "wet lung syndrome" is likely to develop.

There are other factors besides pain which prevent the effective raising of secretions. Primary emphysema, a paralyzed hemidiaphragm, a large drainage tube, partial obstruction of a part of the lower respiratory tract, bronchiectasis or bronchocutaneous fistula—all may help not to the cough of its effective propulsive power. If the remaining lobe on the side of the lobectomy contains residual bronchiectatic tissue, the difficulties of keeping its bronchial system free of secretions are further accentuated. Such a lobe is, as Miller (49) has pointed out, more likely to develop atelectasis than is one which has no bronchiectasis. Temporary clamping of a drainage tube, especially if it is large, adds greatly to the force of a cough. If the patient is unable to raise his secretions, and he is unwilling to try catheter aspiration of the tracheobronchial tree should be done (49) as repeated as often as secretions reaccumulate. It is rarely impossible to pass a catheter through the nose into the trachea, but even though it can be done with ease, if there is any doubt as to the complete removal of secretions or if some complication such as atelectasis should develop, it is better to examine the tracheobronchial tree bronchoscopically and aspirate under direct vision. This can be performed with surprising ease, without moving the patient from his bed, after brief anesthesia of the pharynx and larynx.

A brief physical examination of the chest can provide information which is often indispensable

sooner operative risk. Overholt routinely does a thoracoplasty 6 weeks after resection of the lung in upper lobe for tuberculosis. Johnson advises thoracoplasty 'following pneumonectomy in non-malignant disease especially in young people with long lives ahead of them' (55). It is indeed difficult to advise a patient who has recently had a pneumonectomy for a malignant neoplasm that his operation requires at least two others. No surgeon would do so if he believed recurrence likely. But should the advantages of a thoracoplasty be denied to a man no older than 50 years of age whose neoplasm was small and apparently limited to the lung? It is a complicated question and further consideration of it is beyond the scope of his review.

From 4 to 6 hours after lobectomy gentle suction of from 10 to 15 centimeters of water should be applied continuously to the drainage tube. The remaining lobe will sooner or later fill the cavity and cover the inner opening of the tube. In order to determine when this occurs the tube should be temporarily clamped once each day disconnected from the source of suction and attached to a glass tube in a water sealed bottle. If respiratory oscillations have ceased and cannot be restored by adjustment of the tube at the thoracic wall or by the introduction of a little sterile saline solution with a syringe the tube should be removed since it is serving no useful purpose. Loculated air and further accumulations of fluid can be aspirated by thoracentesis at frequent intervals, at sites properly selected fluoroscopically until the space is obliterated. The persistence of a residual space for more than 10 days in the absence of atelectasis of the remaining lobe or of a bronchopleural fistula is unusual.

At the end of the first week after drainage of a postpneumonic empyema the space can usually be encouraged to obliterate faster if continuous suction is applied through the tube. Negative pressure as low as 150 centimeters of water (11 centimeters of mercury) has been used without demonstrable harm (54). If pressure of more than 20 centimeters of water is employed it should be increased gradually over a period of several days to avoid causing the patient pain. The capacity of the cavity should be measured with saline solutions at intervals of not more than a week, provided that no bronchial fistula is present. Serial Potter-Bucky films in various projections, after injection of iodized oil into the cavity through the tube at weekly intervals, show progressive changes in shape and decrease in size of the empyema space. When it has reached a capacity of from 30 to 50 cubic centimeters, closed drainage is con-

verted to open drainage by cutting off the tube near the skin. The remaining tube is exchanged for a smaller one which is shortened progressively over the course of weeks only as the walls of the shrinking cavity close around it and behind it. The successful treatment of a complicated or chronic empyema is often much more difficult than the simple outline given here would indicate. Various supplementary operations (alone or in combination) such as revision of drainage, extra-pleural thoracoplasty decortication and Schede thoracoplasty may become necessary.

Physiotherapy should begin on the day of operation. All major posterolateral incisions compromise to some degree the large muscles which have to do with motion of the arm and shoulder. Early motion is necessary to prevent spasm, adhesions, and atrophy of muscle and bone. Passive motion of the upper arm in a circular manner while it is elevated as high as the patient can tolerate without actual pain should be done daily during the first postoperative week. As early as the first day patients should be encouraged to help themselves by reaching and turning with the aid of the arm on the side of operation. By the third day free active motion is usually possible to the same extent as that of the good arm. It is particularly important for the patient to carry out his exercises assiduously after each stage of a thoracoplasty when neglect would allow the scapula to become tightly bound to the altered thoracic cage.

The gratifying decrease in the incidence of postoperative complications and of discomforts of convalescence which accrues from early ambulation is now too well recognized to need special emphasis here (22 25 32 57 72). These benefits are not, however, nearly as striking if early rising is postponed until the third or fourth day. At frequent intervals during the first 24 hours the patient must be made to turn from back to side and encouraged to move his legs. In addition to certain commonly accepted contraindications to early ambulation (recent coronary occlusion, danger of hemorrhage, thrombophlebitis) the presence of lowered arterial oxygen saturation, dyspnea, or severe weakness, as well as operations on the pericardium, heart, and great vessels make recumbency advisable for more than the usual length of time. With these exceptions the patient who has had an intrathoracic operation can usually sit on the side of his bed or even in a chair beside it, for two 10 minute periods during the first or second day following operation. Drainage and oxygen tubes are inconvenient but they do not prevent mobilization. Even though the patient

film is not made at the conclusion of such operations as lobectomy and pneumonectomy while the patient is still on the table, it must be obtained at the bedside on the day of operation. A conscious patient with a stable blood pressure should be supported in a sitting position so that a pleural fluid level, if fluid and air are present simultaneously will be visible on the film. Subsequent examinations, which should be carried out at intervals suitable to the case, may be done fluoroscopically and with occasional films. When gastric distention is present especially immediately after operation, a Wangenstein suction apparatus results in prompt relief. Gastric aspiration is a necessary measure for several days following vagotomy because the stomach may become enormously enlarged if it is not drained. For patients who have had an intrapleural or extrapleural pneumonolysis, fluoroscopic control is essential on the day of operation and daily for at least the first few subsequent days. An intrapleural or extrapleural pneumothorax may be lost by the escape of air into the tissues of the thoracic wall within a few hours if air is not injected when it is needed. Following pneumonectomy the mediastinum should be maintained in the midline. An acute overdistention of the remaining lung has occasionally resulted from the use of a water sealed drain (63 77). This is associated with serious lowering of the arterial oxygen saturation. Shift of the mediastinum in the other direction reduces the volume of the remaining lung and prevents adequate ventilation with the same end result, i.e. lowering of the arterial oxygen saturation. Mediastinal displacement in either direction may cause serious cardiovascular and respiratory disturbances (63 13 30).

For the first 5 to 7 days after pneumonectomy when 100,000 units of penicillin should be placed in the pleural cavity daily. If the patient is lying supine the needle may be conveniently placed in the second or third intercostal space at the mid-clavicular line. The intrapleural pressure should be measured at this time, before penicillin is introduced, by the use of a 3 way stopcock and a water manometer. The mediastinal position can then be adjusted if necessary according to the pressure readings and the fluoroscopic findings, by the withdrawal of air or fluid or the addition of air. When aspiration is required, it is preferable to remove air because the fluid is a more permanent space occupying medium. Although it is desirable for the entire hemithorax gradually to fill with fluid, the hydrostatic effect of the dependent fluid collection may be dangerous to patients with a narrow cardiocirculatory margin who can

withstand little mediastinal displacement (6). Such hydrostatic pressure can be controlled of course only by the aspiration of several hundred cubic centimeters of fluid. Adjustments of this nature should be done slowly and tentatively promptly if the patient experiences a feeling of tension within the chest, faintness, an increase in the pulse rate, or a desire to cough. Aspirated fluids should be cultured for pyogenic organisms at least on one occasion. If an extensive thoracoplasty has preceded the pneumonectomy which occasionally the case when the resection was for tuberculosis, the problem of the residual pleural space is largely solved. The postoperative Li is not needed, indeed is not wanted, in the relatively narrow pleural cavity since small accumulations of fluid may produce pressure upon the mediastinal organs. Needling of this fluid is more difficult and dangerous than other thoracentesis. For this reason an airtight, water sealed drain should be employed for several days or until the small pleural cavity is obliterated. Such a drain should be clamped near the skin for several hours postoperatively to retain penicillin in the pleural cavity. When a pneumonectomy is done without a previous thoracoplasty the empty hemithorax becomes partially filled with fluid which undergoes some organization. Resorption of pleural fluid and contraction of the connective tissue gradually cause a decrease in the size of the pleural cavity with traction and displacement of the mediastinum and consequent overdistention of the remaining lung. A year after operation one often finds that the lung has had to come to occupy far more space than it did preoperatively. On rare occasions it may apparently fill the major portion of the entire thoracic cavity. It is true that these changes occur gradually and may not be incompatible with a long life. But pulmonary overdistention or "emphysema" reduces the respiratory function (27) and puts an added burden on the right side of the heart. A further consideration is the effect of stretching upon tuberculous lesions if any should be present in the remaining lung. The patient's comfort and usefulness are thereby compromised and his ultimate life expectancy is unquestionably decreased. Since there is, at present, no satisfactory technique for introduction into the pleural cavity which will prevent this progressive undesirable change, the only alternative is the performance of early thoracoplasty. The extent to which the changes associated with chronic overdistention are reversible is not known. Once they have developed, thoracoplasty sometimes relieves dyspnea (27) but by this time the patient presents

and re-expansion was 6 weeks (64). Of 51 patients with atelectasis following the 154 lobectomies reported by Gowar 14 had a permanent collapse and 9 of these died. The longer the lobe remains atelectatic the more certain is the advent of an extensive empyema. The intrapulmonary infection which follows unrelieved atelectasis often gains access to the large pleural dead space which remains as long as the lobe is unexpanded. More over atelectasis is apparently a frequent primary stage in the development or extension of bronchiectasis. A lobe which was bronchographically normal before operation occasionally develops bronchiectasis after prolonged postoperative atelectasis (75-42).

The most effective preventives of atelectasis are the continued stimulation of the patient to cough the control of pain the use of carbon dioxide and steam and when needed intrabronchial catheter suction or bronchoscopy or both. Efforts must be redoubled when atelectasis is suspected without fear of "worrying" the patient. Since the effect of the continued perfusion of an airless lobe by its share of blood through the pulmonary artery is to reduce the oxygen saturation of blood returned to the left side of the heart oxygen administration should be continued or resumed (66). If the cough is moist and unproductive or if it does not rid the patient of moist sounds, tracheo-bronchial suction by catheter should be used freely. If this fails promptly to relieve the situation bronchoscopic aspiration should be performed repeatedly if necessary. On bronchoscopic examination there is usually no classical mucous plug. The lobar orifice may be found bubbling with mucopurulent secretions, or the obstruction may be distributed in the finer air passages deep within the lobe. The coughing produced by an intrabronchial catheter or bronchoscopic aspirator is usually very helpful in loosening viscid secretions.

Empyema. This is unlikely to follow intrathoracic operations unless (1) the pleura is heavily contaminated during operation from infected lung or other intrathoracic structures (2) intrapulmonary complications occur in the presence of a dead space or (3) bronchopleural fistula or separation of the thoracotomy wound takes place. When a bronchial fistula occurs in the presence of a large collection of intrapleural fluid as following a pneumonectomy drainage of the pleural space should be done as soon as the fistula is detected. Even if fluid under pressure were not aspirated into the lungs, a change in the patient's position could inundate the remaining lung. The opening of a bronchus is almost always followed by an

empyema. In the absence of a fistula an early empyema can sometimes be aborted by frequent aspirations and injections of large amounts of penicillin. After lobectomy the management of an empyema, once it is established, does not differ from that of any postpneumonic empyema. After pneumonectomy the empyema space can be obliterated only by an extensive thoracoplasty. When an empyema occurs after pulmonary resection in which cotton tape was used for the ligation of hilar vessels, the tape is very apt to remain as a foreign body and maintain a small but persistently draining pleurocutaneous sinus until it is removed.

Spread of infection. Postoperative spread of pulmonary infections may follow the spilling of infectious bronchial secretions into undiseased pulmonary tissue. In resection for bronchiectasis this may produce a pneumonic process although it is often difficult to distinguish such a pneumonitis from localized atelectasis. In any case it usually clears promptly with the aid of penicillin therapy. A more grave and indolent spread of infection is occasionally seen following drainage of or resection for lung abscess. Beyond the use of the antibiotics in combination with a sulfonamide there is no specific therapy for these infections. In tuberculosis, it may be impossible to distinguish a bronchogenic spread from a reactivation of latent lesions. Such fresh lesions are not uncommon after the performance of lobectomy and pneumonectomy for active tuberculosis (70-86, 84) and occasionally they occur after thoracoplasty (8) especially when the lesion collapsed by operation was fairly fresh and of a caseous pneumonic type. The presence of an active tuberculous bronchitis at the time of any operation increases the likelihood of spread. It is hoped that the use of streptomycin in selected cases before and after the operation will offer some specific protection. If a serious spread appears after any operation for pulmonary tuberculosis, this drug appears to be indicated. Further surgery should not be carried out until the new lesions disappear or have been relatively stable for at least several months.

The management of many miscellaneous complications that occasionally arise after thoracic operations, such as wound infection, wound disruption, pericarditis, and thrombophlebitis, does not differ from their management under other circumstances and therefore will not be discussed here.

SUMMARY

The occurrence of complications and death after thoracic operations is surprisingly influenced by

is weak or reluctant to rise, he is usually gratified by the rapid return of strength and appetite. Barring complications, the nontuberculous patient is able to walk freely about his room and probably to go to the toilet in less than a week.

Physiotherapy should by no means be confined to the restoration of function to the arm and shoulder after thoracoplasty or thoracotomy. The entire chest must be rehabilitated in order to prevent splinting due to pain and contracting pleural scar (46). Whether after lobectomy the remaining lobe on the side of operation ever quite regains its preoperative function is problematical. If the thoracic cage retracts and its muscular movements are impaired, lobar ventilation and gaseous exchange are certainly correspondingly reduced. A lobe so handicapped remains, in a relative sense, a space filler rather than a significant functional portion of important and irreplaceable tissue. If the disproportion between its circulation and ventilation is great enough it might even become a detriment. When a physiotherapist familiar with postoperative thoracic problems is not available for preoperative instruction and the institution of exercises immediately after operation, these duties must be carried out by the surgical staff. Exercises to promote motion of the affected hemithorax are not difficult to devise. Harken (46) suggests that the first step is to make the patient aware of his immobile chest. For this he must be placed straight in bed with the head, chest and hips aligned. The therapist's hand on the lower thoracic wall is watched by the patient. Faint respiratory motions are exaggerated by the constant firm pressure of the instructor's hand. At the end of expiration an added thrust is given with the hand after which this support is quickly released and the patient should attempt to exaggerate the recoil. He gradually becomes conscious of the area and of its more or less faint respiratory motion and should continue his attempts, with assistance and in a methodical manner to increase its motion. During the recent war both British and American thoracic centers carried a program of rehabilitation to a degree which should be the envy of civilian surgeons (35, 44, 46, 49). To graded bending, twisting and stretching exercises were later added swimming and cross-country running. The patients' progress was graphically demonstrated to them by progressive increase in the measurement of their chest expansion and vital capacity and in their increasing strength and endurance (35). Similar results would be difficult to duplicate outside a disciplined organization where patients can be supervised for weeks. Neverthe-

less, it is a part of the surgeon's responsibility to use every care to avoid leaving his patient with surgically imposed remediable handicap.

COMPLICATIONS

It is difficult to separate the combination of interrelated factors which determine a smooth or stormy postoperative course. Attention to any of the details discussed will often avert ones that may take place after operation. There are, however, certain important complications which occur with sufficient regularity as to merit separate consideration as clinical entities.

Atelectasis. After lobectomy for suppurative disease, atelectasis of the remaining lobe on the side of operation is one of the most frequent of troublesome possibilities. The reported incidence varies from 10 per cent (64) to 33 per cent (7). It occurs almost 2½ times more often on the left side than on the right (41) and is far commoner in the upper lobe after lower lobe lobectomy than in the lower lobe after upper lobe lobectomy (64). Sampson and Collis have found that it occurs in women and men in a ratio of 5 to 2. Gray (43) has stated that it is twice as frequent in children as in adults. The incidence seems to increase after the resection of more than one lobe (75). The chief etiologic factor is the retention of secretions in the lobar bronchial tree. Important factors which contribute to retention of secretions are inadequate coughing due, in part, to pain; a paralyzed diaphragm and mobile mediastinum; a bronchopleural fistula; or the presence of a large drainage tube. Often turning the patient on his good side and having him cough vigorously produces a striking return of previously absent breath sounds. The full blown syndrome is frequently averted in this way. While atelectasis may occur during the immediate postoperative period, the remaining lobe usually appears in the roentgenograms to be satisfactorily aerated during the first 24 to 48 hours. Then, between the second and fifth days (44), when a splinted thoracic wall compromises lobar ventilation and drainage, the breath sounds over the upper chest anteriorly are found to be suppressed and the roentgenogram reveals a sharply opaque lobe. Unless secondary suppuration occurs the symptoms are relatively mild. The temperature and pulse may be somewhat elevated, cyanosis is occasionally apparent but, as a rule, the patient notices little subjective change except possibly mild dyspnea. Atelectasis usually clears within a week if it is promptly and energetically treated. It may, however, persist for many weeks. None of Miler's 8 cases remained permanently atelectatic; the longest interval between collapse

the extent to which many details of preoperative and postoperative management are carried out. Of particular importance is the rapid restoration of the normal anatomical position of the heart and lungs and the maintenance of an efficient coughing mechanism.

The use of antibiotics, fluid and blood replacement, oxygen administration evacuation of bronchial secretions pleural drainage regulation of mediastinal position early mobilization rehabilitation and the prevention and treatment of a few of the common complications have been briefly discussed

which appeared as spotty as the elastic degeneration shown by the orcein stain. In some places the edges of the breaks extended into the deeper layers of the choroid. Separation of the pigment epithelium occurred as a result of a cuticular substance produced by the epithelium and extravasation from the choriocapillaris or by a mixture of glial and fibrous tissue with capillaries derived from the pigment epithelium and the choroid respectively.

Correlation of the clinical and histological findings as discussed in some detail. It is believed that the pathogenesis of angioid streaks is based upon an abnormal fragility and opacification of the lamina basalis of the choroid. Variations in intraocular pressure or slight pressure in the eyeball in such cases may cause the breaks which are visible because of the loss of translucency of the membrane. The frequent association with pseudoxanthoma elasticum (not present in this case) suggests a primary inferiority of the elastic tissue in the body. Deposition of calcium into the membrane seems to be essential to all except the earliest manifestations of the disease.

The Effect of Aluminum and Its Alloys on the Eye:
A Report Presented to the Vision Committee
of the Medical Research Council L. H. SAVIN
Brit J Ophth 1947 31 449

The author reports a case in which a piece of aluminum metal was observed over a period of 3 years as it lay on the retina of an only eye in a young British sergeant. At first the metallic object was bright and silvery but later it presented a white coating which was believed to be aluminum hydroxide. After shifting twice and leaving a retinal imprint each time it eventually disintegrated into a white powder.

Another case acted in a similar manner.

The experimental introduction of fragments of aluminum and aluminum alloys ranging in size from 0.3 to 20 mgm. into the anterior and vitreous chambers of rabbits revealed that there was no clinical difference between the behavior of pure aluminum and that of various alloys, but the ocular reaction tended to be more severe in the case of the higher doses. In other words there is much less toleration for larger fragments than for smaller ones.

All of the fragments became coated with white powder, yellowish exudate, fibrin and in late cases with jelly. Powdering and fragmentation occurred late, and in 6 cases the fragment was completely absorbed.

The effects on the eye included the development of the following lens opacities in 28 eyes: striae, dots, vacuoles, and irregular opacities. Of the opacities 5 were anterior capsular, 6 anterior cortical, 4 posterior cortical, 2 capsular imprints, and 3 complete cataracts. Quiet uveitis occurred in many cases. There were 10 cases of posterior synechias, 2 cases of iris bombe and 14 cases of atrophy of the iris. The fundus presented pigmentation in 23 cases, localized choroiditis in 6 and retinitis proliferans in 3 cases.

Histologic investigations revealed hyalinization and vascularization of the cornea, iritis, and atrophy and abnormal pigmentation of the iris. Pathologic changes in the retina and choroid were present in many instances.

As a result of the clinical and experimental investigation it is concluded that the eye is by no means inert to aluminum.

Aluminum and its alloys produce widespread changes in the eye regardless of the size or position of the fragment. Although aluminum and its alloys are not so destructive to the ocular tissues as iron and steel, whenever possible they should be removed surgically. This applies especially to foreign bodies in the anterior chamber. However in many cases technical difficulties preclude removal for example intravitreal fragments may have to be left alone unless their size is such that loss of the eye would be inevitable.

Ocular Infections. JOHN G. BELLON and CHESTER J. FARMER, *J Am Ass* 1947 135 491

The authors report that streptomycin is useful for various infections caused by organisms either insensitive or resistant to sulfonamide compounds and penicillin. Streptomycin is bacteriostatic against certain gram positive organisms as well as against a variety of hitherto resistant gram negative forms.

For acute conjunctivitis drops of streptomycin (10,000 micrograms per cubic centimeter) are instilled at 1 hour intervals during the waking hours (8 or 9 times a day) and continued for a period of 8 days.

Penetrability of the cornea to streptomycin may be increased by abrasion, inflammation, ion transfer, and by wetting agents.

Streptomycin is safe and nonirritating to the surface of the eyeball in concentrations up to 10,000 micrograms per cubic centimeter. Higher concentrations delay regeneration of the epithelium and may promote scarring and vascularization of the cornea.

Intracocular injections of 500 micrograms of streptomycin in 0.1 c.c. of isotonic sodium chloride solution may be administered. If the drug is injected within from 6 to 8 hours after inoculation as few as 25 micrograms of streptomycin have been found effective in the prevention of experimental beta hemolytic streptococcal infections of the vitreous.

Experimentally corneal infections caused by the *Bacillus pyocyaneus* are completely controlled by 3 instillations of streptomycin drops (10,000 micrograms per cubic centimeter) if made at 2 hour intervals within from 6 to 8 hours after inoculation.

Streptomycin was employed in 23 clinical cases of ocular infection. It was exceptionally effective in a case of primary meningococcal conjunctivitis and in a case of *Bacillus pyocyaneus* infection of the cornea.

In most cases of acute or chronic infections of the conjunctiva and cornea organisms are rapidly eliminated by streptomycin therapy and in the absence of complicating factors rapid healing ensues.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

The Lamina Cribrosa and Its Nature. MARIAN WILCZEK *Brit J Ophth.* 1947 3 557

The author discusses our knowledge of the nature of the lamina cribrosa. This structure which has been likened to a membrane of India rubber is generally accepted to be a semi-independent scleral structure of which the dimensions are known. Its planes, thickness and backward curve have all been measured.

To understand the structure of the cribriform lamina it is necessary to know its relation to the sclera and septa of the optic nerve. The cribriform lamina develops comparatively late, as late as the end of fetal life or even the beginning of extrauterine life. Trabeculae of connective tissue grow into the nerve and disk from all directions from the pia mater from the sclera in the scleral canal, and from connective tissue which accompanies the central vessels.

Wilczek introduces the concept of the "nest" of the optic disk. Bundles of nerve fibres are separated by neuroglial tissue. Connective cells grow into these neuroglial septa to supply the nerve with vessels. Connective tissue divides the nerve into smaller and smaller bundles and forms first, second and third grade septa but still smaller septa are formed by neuroglia. There is no sharp division between the pia or dura mater and the sclera as meningeal sheaths pass into and coalesce with the sclera.

One of the most important functions of the cribriform lamina is considered to be fixation of the optic nerve in the scleral canal, where the optic nerve is exposed to the danger of being pulled. The cribriform lamina should not be considered as an independent structure but as the foremost and strongest part of the septal system of connective tissue of the nerve.

EYE

Ocular Injuries in Soldiers. BENJAMIN RONES and HELENER CA F ELL WILDER. *Am. J Ophth.* 1947 30 1143.

Of approximately 4,000 eyes enucleated in army hospitals between Pearl Harbor and V J Day 204 were removed because of nonpenetrating ocular injuries, 47 occurring during combat or training and 57 occurring before the patient entered the service.

The interval between injury incurred during combat or training and enucleation varied from less than 1 day to 3 1/4 years. The eyes enucleated on the day of injury had fresh hemorrhage as the dominant finding. As the time interval between the date of injury and enucleation lengthened organization of

the hemorrhage became more apparent, the signs of chronic inflammation and secondary glaucoma increased and atrophic changes took place. Iru, pupillary and cystic membranes, calcium deposits in the lens, and phthisis bulbi were observed. Cruciate cataracts, dislocated lenses, detachment of the retina and choroid, and evulsion of the eye nerve were present in many eyes.

In the cases of the 57 eyes that had been operated before induction the interval between injury and enucleation was from 4 to 38 years. Chronic endophthalmitis was the most frequent finding in this group with cataract detachment of the retina and choroid and secondary glaucoma following in the order. A great variety of degenerative and inflammatory changes were recorded. The eyes had an endophthalmitis due to tissue trauma and subsequent hemorrhage but in which the condition was not complicated by surgery or secondary infection. There was a paucity of cellular response in contrast to the cellularity of infectious uveitis with lymphocytes and plasma cells as the dominant cell types. Exudative response was marked and resulted in the formation of synechiae and pupillary and cyclitic membranes.

ROBERT H. JOHNSON, M.D.

Angioid Streaks. BENJAMIN A. KLEIN. *Am. J Ophth.* 1947 30: 955

Five clinical cases of angioid streaks are recorded with an additional clinical case in which there was a later histopathological study following enucleation of both eyes after death of the patient from aneurysms with severe cerebral hemorrhages.

Previous histological findings recorded by Beck and Hagedoorn were confirmed, and some new observations made. As previously noted, the degeneration of the elastic portion of Bruch's membrane leading to ruptures and dehiscences was sufficient to render the membrane opaque. Also observed as in the 2 previously reported histological studies, was a coexisting vascular disease affecting chiefly the posterior ciliary and choroidal vessels. The positive iron stain of the lamina basalis in the posterior polar region previously mentioned, was also found in these eyes.

A study of the morphological characteristics of the eyes in the present report showed that the earliest ruptures were limited to the elastic portion of the membrane with the cuticular layer the pigment epithelium and the overlying retina remaining intact. There were two types of defects: (1) abrupt vertical severance and (2) oblique dehiscence, influenced in character perhaps by the previous calcification or degeneration of the elastic tissue. A positive Kossa stain demonstrated the calcification

In the author's 7 cases there was more or less clearing of the corneal opacities without further ulceration of the cornea. The shrunken fornices were deepened. ROGER H. JOHNSON M.D.

Vertical Motor Anomalies. Discussion of Miss Kramer's Paper. MARY EVERIST KRAMER and E. A. W. SHEPPARD. *Am. J. Ophth.*, 1947 30 1113

This article is based on the study and treatment of 67 cases of vertical squint most of which were complicated by lateral deviation. The author listed 5 types of recognized vertical deviations (1) concomitant, (2) vertical, due to unclear and infranuclear paresis, (3) vertical, due to supranuclear paresis, (4) pseudoparetic hyperphoria, and (5) vertical of dissociated type. The value of making an accurate diagnosis was stressed.

In concomitant hypertropia the amount of vertical deviation is approximately equal in the whole field of fixation and, often fusion training will relieve the patient of his symptoms but will not correct the hypertropia. At this time attention should be given to the lateral fusional range. The treatment of a paretic hypertropia is not orthoptic but medical and surgical. Fusional training however is often highly beneficial in recovered cases of paresis in that it makes for better co-ordination of the 2 eyes in binocular vision. The vertical deviations due to a supernuclear paresis are not within the realm of orthoptics and therefore are not discussed. Pseudoparetic hyperphoria is characterized by overaction of the inferior oblique muscle without a deficiency of the superior oblique muscle of the same eye or the superior rectus muscle of the opposite eye. Hyperphoria is not present in the primary position. No orthoptic treatment is indicated unless the patient is having symptoms although most vertical phorias have a coexisting lateral component which when corrected frequently causes the disappearance of the pseudoparetic hyperphoria. Dissociated vertical divergence is characterized by a variable hyperphoria of the eye which is not fixing and is the most amenable of all vertical motor anomalies to orthoptic treatment. Surgery is contraindicated.

Orthoptically the treatment of these vertical phorias is essentially the establishment of good fusion and the correction of the amblyopia which is frequently present. Dissociation training aids in teaching voluntary control of the vertical deviation. A cure has been effected only after the dissociation exercises both for near and distance can be accomplished with comparative ease and good binocular stability is established. ROGER H. JOHNSON M.D.

Mycotic Obstruction of the Nasolacrimal Duct (Candida Albicans). MAX FINE and WILLIAM S. WARING. *Arch. Ophth.*, 1947 38 39

The authors present their observations in 2 cases of obstruction of the nasolacrimal duct by fungi. Fungi especially streptothrix and leptothrix often produce obstruction of the lacrimal passages. In most cases the obstruction consists of mycotic con-

cretions in the lacrimal canaliculi in only a few cases is the obstruction situated in the nasolacrimal duct.

An intensive study of the mycotic flora of normal and of diseased eyes by Fuzakas revealed that, in descending order of frequency the following fungi were recovered most often: *Penicillium Torula*, *Alternaria Schizosaccharomyces hominis*, *Haplosporidium* and *Aspergillus*. *Actinomyces* is most often encountered in concretions of the canaliculi.

Two cases of mycotic obstruction of the nasolacrimal duct are reported. The yeast was identified as *corpus albicans* in 1 case and the organism was not identified in the other case.

Immediate and spontaneous recovery followed extraction of a castlike obstruction of the duct.

JOSHUA ZUCKERMAN M.D.

Local Penicillin Therapy of Hypopyon Formation with Special Reference to the Use of Subconjunctival Injection. ARNOLD SOREY and HOWARD REED. *Brit. J. Ophth.*, 1947 31 518.

The authors discuss not only the ocular indications for the use of penicillin locally but also the optimal methods for its employment locally.

In order to be effective, drops have to be instilled at frequent intervals. Lamellae have not proved satisfactory. Ointments present difficulties concerning the best base to employ. Solid penicillin is effective when applied directly to an infected ulcer (Juler and Young, 1945).

Subconjunctival injection of penicillin was found superior to all other modes of applying penicillin. The following method of treatment is employed:

1. A smear is taken for culture purposes.
2. The conjunctiva is anesthetized by instillation of several drops of a local anesthetic.
3. A half cubic centimeter of a 2 per cent novocain solution and 0.5 c.c. of epinephrine hydrochloride (1:1000) is injected into an ampoule containing 100,000 units of white crystalline penicillin. A half cubic centimeter is then withdrawn and injected subconjunctivally.
4. Atropine is instilled and the eye may be bandaged.
5. Injections are repeated at 6 hour intervals for 3 days, a total of 12 injections being given in all cases. If indicated another 4 injections may be given over an additional day.
6. After the injections are discontinued penicillin ointment in a concentration of 100,000 units per gram is introduced every 4 hours day and night. The ointment is made with a specially prepared base of 90 parts of petroleum jelly and 10 parts of liquid paraffin. Use of the ointment is continued for 48 hours after apparent clinical cure.

In other words from 12 to 16 subconjunctival injections are administered at intervals of 6 hours. Each injection contains 50,000 units of penicillin (dissolved in 0.25 c.c. of 2 per cent novocain and 0.25 c.c. of 1:1000 adrenalin). This treatment is followed by the introduction of penicillin ointment every 4 hours in a concentration of 100,000 units per gram.

The Distribution of Penicillin in the Eye after Subconjunctival Injection. ARNOLD SOREBY and J. UNGER. *Brit. J. Ophth.* 1947 31 517

The authors discuss the distribution of penicillin in the eye following subconjunctival injection of the drug. Adequate intraocular concentrations of penicillin can be achieved by systemic administration of massive doses, by the application of highly concentrated ointments, and by subconjunctival injections. The highest and most persistent intraocular concentration can be obtained by subconjunctival injection especially when the penicillin is combined with epinephrine hydrochloride solution (1:1000) as a solvent.

Subconjunctival injection of 50,000 units of penicillin produces high intraocular levels. The introduction of ointment in concentration of up to 40,000 units per gram does not maintain any adequate intraocular levels after 2½ hours, neither does systemic administration of the drug. The overwhelming advantages of subconjunctival injections are beyond question.

It is pointed out that an injection of 50,000 units is preferable to one of 10,000 units because the former not only gives a considerably and disproportionately higher level of intraocular concentration but this level is maintained for a longer period of time. Injections should be given at intervals of 6 hours to maintain adequate levels.

Normal saline solution as a solvent is unsatisfactory because penicillin dissolved in it becomes a hypertonic solution. Adrenalin as a solvent has many advantages. Two per cent novocain hydrochloride solution may also be used as a solvent in painful eyes.

Streptomycin in Ophthalmology J. G. BELLONS and C. J. FARMER. *Am. J. Ophth.* 1947 3 115

The authors describe the use of streptomycin in ophthalmology. Although thousands of strains and species of actinomyces, fungi, and bacteria have been investigated for antibiotic action and therapeutic usefulness, only penicillin and streptomycin have proved to be of therapeutic importance. Penicillin is more valuable, but streptomycin has been found to be superior to penicillin in the control of certain specific organisms.

Streptomycin is safe and nonirritating to the surface of the eyeball in concentrations up to 10,000 mcgm. per milliliter. Higher concentrations delay regeneration of the epithelium and promote scarring and vascularization of the cornea.

Intravitreal injections of 500 mcgm of streptomycin in 0.1 ml. of saline solution are well tolerated. Effective therapeutic concentration is maintained in the vitreous for more than 24 hours by intraocular injection of 100 mcgm of streptomycin.

Because local application of streptomycin decreases the amount of secondary infection accompanying vaccinia infections of the cornea, treated eyes become less scarred and less vascularized.

A Statistical Study of Glaucoma. J. C. HARRIS. *J. Ophth.* 1947 30 187

The author made a statistical study of glaucoma. He reports that at the University Eye Clinic in 1930 between 1930 and 1939 among 2,177 adults (55 per cent men, and 45 per cent women) there were 2167 cases of glaucoma divided as follows: 120 cases of glaucoma simplex of which 63 per cent were in men and 38 per cent in women, and 193 cases of congestive glaucoma, 55 per cent of which were men and 64 per cent in women. Glaucoma simplex constituted 53.4 per cent of all of the cases, all congestive glaucoma constituted only 6.6 per cent.

Hypermetropia occurred in fully 55 per cent of the cases, emmetropia in 50 per cent, and myopia in 2 per cent. Almost 5 per cent of the cases were astigmatic. In this series of cases the preponderance of emmetropia was very marked.

Three hundred and seventy five cases (8.5 per cent of 439 examined for the possible presence of cataract of the lens capsule presented this condition. In the 53 cases of unilateral glaucoma in which cataract was found on only one side. It was always in the glaucomatous eye.

JOSHUA ZUCKERMAN, M.D.

An Operation for Trachomatous Pannus. H. L. RABDO. *Am. J. Ophth.* 1947 30 109

The author described a surgical method in the treatment of severe and persistent cases of trachoma with pannus formation. Since he believes that the presence of capillaries in the superficial layers of the cornea is essential to the formation of the trachomatous pannus, and since these capillaries are not spring from the blood vessels of the conjunctiva, he reasoned that the best treatment for this condition would be to remove the conjunctiva from the limbal region permanently. The operative procedure was as follows:

The conjunctiva was incised as close to the limbus as possible and then dissected all around to the limits of the fornices. The subconjunctival tissue was then carefully removed for about 6 millimeters around the limbus to leave a very thin sclera. The remnants of the conjunctiva at the limbus were curetted away and the active blood vessels in the cornea were split with the point of a catgut knife. One needle of a double armed silk suture was inserted in the scleral side of the conjunctiva in the superior temporal quadrant about 10 millimeters from its margin, passing parallel to the margin for about 6 millimeters and then coming back through the conjunctiva. Both ends of the suture were then carried up between the sclera and the conjunctiva to emerge through the skin under the brow where they were tied over a small roll of gauze. The procedure was followed in all 4 quadrants. The conjunctiva was held at an equal distance from the limbus all around the cornea.

The advantage of this operation was that there was a permanent disappearance of the blood vessels from the cornea with a consequent recovery from the pannus.

der to relieve the most nauseating and distressing symptoms—diplopia. Diplopia may be associated with mental confusion and headache. Following resection of the vertical deviation by surgical procedures, binocular reflexes assisted by orthoptic training maintain fusion within the range of normal ocular movement. Orthoptic exercises prevent suppression of the affected eye and maintain the tone of the extraocular muscles. If the deviation is marked it may be corrected in stages to avoid possible overcorrection with resultant relative paresis. After operation exercises will strengthen the binocular reflexes and increase the fusion hold of the newly restored binocular vision. Residual defects can then be corrected.

Neely points out that traumatic diplopia is not an uncommon sequel to head injuries; that the diplopia usually results from paresis, not from paralysis of an extraocular muscle; that the diplopia is caused by a "closed" head injury rather than by a penetrating head wound; that the vertically acting muscles are most often affected; that injuries to the orbit may be overlooked or masked by swelling of the surrounding tissues; and that roentgen ray diagnosis of fractures of the floor of the orbit is difficult unless stereoscopic plates are taken.

Fractures which involve the orbit require restoration of the normal anatomy of the parts and building up of the orbital floor by means of a bone inlay. To overcome the residual diplopia and restore binocular single vision, eye muscle surgery aided by orthoptic exercises is required.

NOSE AND SINUSES

Role of Penicillin in the Management of Acute and Chronic Frontal Sinusitis. KENNETH M. KAHN, *Arch. Otolaryng., Chic.* 1947 46 293

Seven patients with sinus disease were treated with penicillin plus indicated surgical measures. In the 6 cases in which supuration was present, surgical measures were necessary for cure. Penicillin given in these cases prevented dissemination of infection by its bacteriostatic action. Twenty five thousand units were given intramuscularly every 3 or 4 hours. One patient with a complicating meningitis was given 50,000 units intramuscularly every 3 hours and 15,000 units intrathecally daily. In 3 cases penicillin filled into the wound through fixed urethral catheter was considered to aid in early primary wound cure.

JOHN R. LINDSAY, M.D.

Regenic Tumors of the Nose and Throat. GORDON B. NEW and KENNETH D. DEVIDE, *Arch. Otolaryng., Chic.* 1947 46 163

In the last 27 years at the Mayo Clinic, 33 cases of regenic tumors in the nose or throat have been treated. These include 9 cases of developmental and 24 cases of neoplasm.

There were 6 cases of meningocele. Four of the lesions were large pulsating compressible tumors at the root of the nose. In an

other case there was a small, firm rounded mass at the root of the nose, which was thought to be a dermoid cyst. At the time of operation it was recognized as a meningocele and the pedicle was ligated. In 1 case the tumor presented as a cyst of the nasal cavity. Meningoceles are neurosurgical problems.

There were 3 cases of encephalocele. The tumors were firm, rubbery, round congenital tumors at the root of the nose lying just to the right of the midline. Small external encephaloceles with no intranasal or intracranial connections are best removed through a horizontal incision over the root of the nose. These tumors are not encapsulated and must be removed by sharp dissection, care being taken to remove all of the tumor.

An intranasal encephalocele may have intracranial connections. For this reason any surgical procedure for its removal must furnish adequate exposure so that the distal pedicle or attachment of the tumor may be ligated or electrocoagulated if there is any evidence of intracranial connection.

There were 19 neurofibromas. Among these 19 cases there were only 4 of Recklinghausen's disease. Neurofibromas of the oropharynx, hypopharynx and tonsillar region are best attacked surgically through the mouth after preliminary ligation of the external carotid artery on the side involved. They shelled out easily from the capsule and rarely recur. An occasional pharyngeal neurofibroma may be so large that it is necessary to do preliminary tracheotomy. It is usually necessary to approach these large tumors through an external incision. If the location of the tumor prevents shelling it out, destruction of the tumor by surgical diathermy may be necessary.

There was only 1 ganglioneuroma. This was a firm tumor involving the left basal region of the tongue extending forward to a point opposite the bicuspid area, back almost to the tip of the epiglottis, and down through the floor of the mouth where it presented in the left submaxillary region. After preliminary ligation of the left external carotid artery the tumor was removed through the mouth.

There were 4 cases of meningioma. In 3 cases the tumor was in the frontal sinus and in 1 case it was located subcutaneously at the root of the nose. Meningiomas in the nasal sinuses and located subcutaneously at the root of the nose are best removed by surgical diathermy.

MOUTH

Prosthetic Restoration of Palate. A. H. KAZANTZAK, *J. Oral Surg.* 1947 5 181

The author discusses the value of various types of prosthetic appliances which may be utilized along with or following surgical procedures for the correction of deformity of the upper jaw.

Deformities of the maxilla may be congenital or acquired. Cleft palate is the most common congenital deformity. Prostheses are of value when surgery results in failure or only partial success. After suc-

It is pointed out that if no substantial response is obtained at the end of 48 hours further injection of penicillin is useless.

A series of 66 patients with hypopyon was treated with penicillin. There were 39 cases of infected corneal ulcer 18 of which were treated by subconjunctival injections of penicillin in doses of 30,000 units with or without the application of penicillin ointment. Infected corneal ulcers responded well to treatment. Eighteen of 21 cases of infected corneal ulcer with hypopyon responded to subconjunctival injections. Hypopyon associated with herpetic or neuropathic keratitis gave no response. Hypopyonitis required no treatment other than atropine.

General sulfonamide therapy was used in 3 patients when subconjunctival injections of penicillin were inadequate
 JOSHUA ZUCKERMAN, M.D.

Bilateral Uveitis from Horse Serum. T. F. SCHLAEGEL, JR. *Am. J. Ophth.* 1947 30 1 5

The author describes the development of bilateral granulomatous uveitis in rabbits after the use of normal horse serum.

In every case in which the right eyes of rabbits were injected with serum and later given repeated large doses intravenously the reaction was severe in the injected eyes and moderate in the un.injected.

The uvea revealed infiltration by lymphocytes, large mononuclear phagocytes, plasma cells, and epithelioid cells. Injected eyes developed replacement fibrosis and involvement of the retinas, whereas the infiltration in the un.injected eyes remained fresh and the retinas were not affected.

A second series of experiments was performed to elucidate the mechanism of this contralateral response. The rabbits received the original injection intracutaneously instead of into the right eye.

Not only the clinical but also the microscopic reactions in the un.injected eyes of the first series were significantly greater than the reactions in the un.injected eyes of the second series. The cause of this apparent superiority of the eye over the skin for predisposition to a reaction in un.injected eyes was not determined.

Penicillin Therapy of Experimental Infections of the Lens and Vitreous with *Clostridium Welchii*. LEON C. HOSKINS. *Arch. Ophth.*, Chic. 1947 38 30

The author discusses penicillin therapy of infection of the eye by *Clostridium welchii*. Infections of this type which are relatively common among battle casualties are now effectively controlled by penicillin. Because penicillin iontophoresis failed to check infection of the lens by this organism, experimental infection of the lens and vitreous was undertaken.

Hoskins found that direct injection of penicillin into the lens and vitreous satisfactorily controlled infections with the *Clostridium welchii* if the therapy was instituted within 3 hours after the inoculation.

The results were less favorable when the interval between the infection and the treatment was increased to 6 hours.

In a series of 3 hour cases a beneficial effect was obtained with only moderate damage to the structures of the eye.
 JOSHUA ZUCKERMAN, M.D.

Dicumarol and Rutin in Retinal Vascular Disorders. ARTHUR L. MACLEAN and GORDON I. BRANNEN. *Am. J. Ophth.* 1947 30 1093

The purpose of the authors was to present to concomitant use of dicumarol and rutin in retinal retinopathies. The mechanism of retinal vessel occlusion was presented as a slowing of the blood flow followed by the formation of a thrombus on the endothelium upon which cells and fibrin are deposited so that an organized thrombus protrudes into the lumen of the vein. When dicumarol is administered orally the prothrombin activity of the blood is reduced and intravascular thrombus as well as intravascular coagulation is inhibited in this manner the enlargement of the clot by continued fibrin deposition may be prevented. The prothrombin, if its growth is checked, may leave less for the passage of blood. Rutin was used to decrease capillary fragility when present.

In this series of 21 cases dicumarol was given in dosages to maintain a coagulative activity level of 30 per cent of the normal. In more than one-half of the cases rutin was usually given orally at the same time in 60 milligram doses daily. The dicumarol produced a minimum of untoward side reactions and no toxic manifestations were observed from its rutin.

The present series of cases of various retinopathic conditions manifested a definite decrease in the prothrombin clotting time compared to normal controls. Dicumarol and rutin therapy in a case of tributary occlusion showed an increased rate of improvement, but in 6 cases of central vein occlusion the rate of recovery was variable. Four patients with diabetic retinopathy presented improvement in their visual acuity and absorption of hemorrhages when treated with dicumarol and rutin. The retinopathic condition manifested by macular and perimacular edema with attenuated vessels was decreased in a short time with rutin and dicumarol. Two patients with Eales disease were found to have a strongly positive Goethlin index and rutin alone produced improvement.

The primary etiologic factor of degenerative retinopathy probably rests upon vascular sclerosis and the secondary process of thrombosis. Dicumarol therapy produced an improvement in all cases of this type.

The author describes the development of bilateral granulomatous uveitis in rabbits after the use of normal horse serum.

In every case in which the right eyes of rabbits were injected with serum and later given repeated large doses intravenously the reaction was severe in the injected eyes and moderate in the uninjected.

The uvea revealed infiltration by lymphocytes, large mononuclear phagocytes, plasma cells, and epithelioid cells. Injected eyes developed replacement fibrosis and involvement of the retinas, whereas the infiltration in the unaffected eyes remained fresh and the retinas were not affected.

A second series of experiments was performed to elucidate the mechanism of this contralateral response. The rabbits received the original injection intracutaneously instead of into the right eye.

Not only the clinical but also the microscopic reactions in the uninjected eyes of the first series were significantly greater than the reactions in the uninjected eyes of the second series. The cause of this apparent superiority of the eye over the skin for predisposition to a reaction in uninjected eyes was not determined. **JOSEPH ZUCKERMAN, M.D.**

Penicillin Therapy of Experimental Infections of the Lens and Vitreous with Clostridium Welchii. LEON C. HOSKINS. *Arch. Ophth.* Chic., 1947 38 50

The author discusses penicillin therapy of infection of the eye by *Clostridium welchii*. Infections of this type which are relatively common among battle casualties are now effectively controlled by penicillin. Because penicillin iontophoresis failed to check infection of the lens by this organism, experimental infection of the lens and vitreous was undertaken.

Hoskins found that direct injection of penicillin into the lens and vitreous satisfactorily controlled infections with the *Clostridium welchii* if the therapy was instituted within 3 hours after the inoculation.

The results were less favorable when the interval between the infection and the treatment was increased to 6 hours.

In a series of 3 hour cases a beneficial effect was obtained with only moderate damage to the structures of the eye. **JOSEPH ZUCKERMAN, M.D.**

Dicummarol and Rutin in Retinal Vascular Occlusion. ARTHUR L. MACLEAY and CHAS. I. BRAMWELL. *Am J Ophth.* 1947 30 1043

The purpose of the authors was to present a concomitant use of dicummarol and rutin in vascular retinopathies. The mechanism of retinal vascular occlusion was presented as a slowing of the blood flow followed by the formation of a reorganized occlusion on the endothelium, upon which cells and fibrin are deposited so that an organized thrombus passes into the lumen of the vein. When dicummarol is administered orally the prothrombin activity of the blood is reduced and intravascular thrombus as well as intravascular coagulation is inhibited in this manner the enlargement of the clot by further fibrin deposition may be prevented. The potential thrombus, if its growth is checked, may leave a scar for the passage of blood. Rutin was used to decrease capillary fragility when present.

In this series of 35 cases dicummarol was given in doses to maintain a coagulative activity index of 50 per cent of the normal. In more than one-half of the cases rutin was usually given orally at the same time in 60 milligram doses daily. The dicummarol produced a minimum of untoward side reactions and no toxic manifestations were observed from the rutin.

The present series of cases of various retinopathies manifested a definite decrease in the prothrombin clotting time compared to normal controls. Dicummarol and rutin therapy in a case of tributary occlusion showed an increased rate of improvement, but in 6 cases of central vein occlusion the rate of recovery was variable. Four patients with diabetic retinopathy presented improvement of their visual acuity and absorption of hemorrhages when treated with dicummarol and rutin. The retinopathic condition manifested by macular and perimacular edema with attenuated vessels was cleared in a short time with rutin and dicummarol. Two patients with Eales disease were found to have a strongly positive Gollin Index and rutin alone produced improvement.

The primary etiological factor of degenerative retinopathy probably rests upon vascular sclerosis and the secondary process of thromboses. Dicummarol therapy produced an improvement in all cases of this type. **ROBERT H. JOHNSON, M.D.**

The Treatment of Traumatic Diplopia J. C. Voss *Brit. J. Ophth.* 1947 3 58

The author reports his findings concerning the incidence and causes of accommodative asthenopia and discusses the treatment of traumatic diplopia.

Before the war there was no recognized technique for correction of traumatic diplopia.

As far as the vertically acting muscles are concerned it is not necessary to obtain orthophoria in

cessful operations have been performed in infancy retraction of the upper middle half of the face and gross irregularities of the teeth often result. Artificial palates are of two types those which are movable and under control of the muscles of the soft palate, and those of the stationary type which form contact on their lateral and posterior surfaces with the muscles of the palate and pharynx. The movable appliance may leak air at the point of contact with its supporting denture and occasionally requires repair. The stationary denture creates more strain on supporting teeth and is not desirable in the absence of adequately sound teeth.

Retraction of the upper jaw is often seen in young adults because of a lack of underlying support of the alveolar bones. The Eastlander Abbe operation has given good results in those patients with an underdeveloped upper lip. The operation consists of a two-stage transfer of a measured triangular flap from the midline of the lower lip to the upper lip.

Acquired deformities occur as the result of injury or disease or by operative treatment for malignancy. Use of an immediate denture in operative defects prevents secondary contractions and adhesions of the soft tissue and contributes to the patient a comfort. Prosthetic appliances may be anchored to the remaining alveolar ridges, palate and teeth. Spaces leading to the nasal cavity may also be used as means of retention. It is sometimes advisable to incise adhesions of the mucous membrane and apply a skin graft within the oral or nasal cavities to give better membranous lining for toleration of the denture. Spiral springs with attachments from the lower jaw to the upper prosthesis are of some value when other methods of retention fail. Surgical measures are necessary to make the prostheses possible and should be made to harmonize with prosthetic procedures to be used in each case.

Ten case histories with excellent diagrams and photographs illustrating different types of prosthetic appliances are presented. JOHN R. LINCOLN, M.D.

Partial Denture Prosthesis for War Injuries. LOUIS EMORY. *J Am Dent Ass* 1947 35 634.

The surgical treatment of maxillofacial injuries has received a great deal of notice in the literature but, as the author of this report says, little or no reference has been made to the artificial restoration of lost parts of the jaw and face. The restoration of function and esthetic substitution for the lost parts is the duty of the well trained dentist, continually working hand in hand with the surgeon. The author emphasizes the necessity for the early combined efforts of these two but points out that a thorough understanding of the basic principles and engineering skill of the most exacting prosthodontic type are required and the work may perhaps require a long period of time. In other words no case is static and each one may require—more often than not—constant alteration not only to fit in with the changing surgical situation but also to assure comfort and to fulfill the functional requirements.

This article deals only with partial denture restorations. The illustrations and discussion give a clear, though concise, description of the conditions which may be encountered. The bibliography is fairly complete. WILLIAM G. SMITH, D.D.

NECK

Papillary Cystadenolymphoma. KAN-GUO LIAO. *Acta radiol., Stockh.* 1947, 26: 22.

Cystadenolymphoma occurs principally in elderly persons, their average age being about 60 years. The great majority of the patients have been men. This condition progresses slowly generally over a period of several years, and the tumor may become quite large. A differential diagnosis between this condition and other tumors of the parotid gland is most impossible. The diagnosis is made by microscopic examination. Most of these tumors have a distinct capsule and may be easily shelled out. Incurrences were noted in only 3 cases and the recurrence resembled the original tumor. No cases have shown malignant degeneration. Cystadenolymphoma has no typical macroscopic characteristics. The microscopic findings are highly characteristic, one portion being epithelioid degeneration and the other being lymphoreticular resembling a lymph node.

Nine case reports are presented in abstract. Two tumors had been observed primarily in the parotid area, only 5 were in the submandibular region and none was in the sublingual region.

RICHARD J. BECKETT, JR. M.D.

Simultaneous Chromaffin Tumors of the Carotid Body and the Glomus Jugularis. G. F. KIRK. *Arch. Path., Chic.* 1947 44: 15.

A case is presented in which there were multiple tumors arising in the chromaffin system. One tumor was found in the carotid body on the right side of the neck and the other tumor was found in the petrous portion of the temporal bone. This recently recognized body is known as the glomus jugularis. It appeared that the tumor of the petrous portion of the left temporal bone had been present for 50 years before the tumor of the right side of the neck was discovered.

In the report of the single case, there was nothing unusual in the physical examination except the tumors. Biopsy specimens taken before death showed a pathology similar to that of the tumor found post mortem. The tumor of the petrous portion of the left temporal bone would appear to have been present for at least 50 years since it was completely removed at the primary mastoidectomy.

RICHARD J. BECKETT, JR. M.D.

Intrinsic Cancer of the Larynx. Review of a Series of Cases. V. E. NIXON. *Proc. R. Soc. Med. Lond* 1947 40: 55.

Among 503 lesions of the upper portions of the respiratory and alimentary tracts, observed by the

author over a period of 20 years, 93 were intrinsic and 94 were extrinsic laryngeal cancers.

Of the intrinsic cancers 54 were unilateral (41 cordal, 7 subglottic and 6 supraglottic) and 39 were bilateral (10 limited and 29 diffuse). There were 20 males and 3 females. The ages of the patients ranged from 26 to 80 years the majority being from 40 to 60 years. Age had no apparent relation to the prognosis since the percentage of "cures" was similar in all age groups. The lesions were squamous cell carcinomas except for an epithelioma (Broders group 4) in 1 case. Seventy nine of the 93 patients were treated by the author.

The pathological sections of 42 lesions were graded according to Broders classification. Success is defined as absence of recurrence at the end of 5 years. Results were listed as promising if there was no recurrence during a period of observation of less than 5 years.

In group 1 there were 4 failures and 4 successes in group 2 9 failures and 14 successes in group 3 4 failures and 4 successes in group 4 3 failures (no successes).

Of 35 patients treated for unilateral cord cancer 20 were cured and in 11 patients the results were promising of 5 with unilateral subglottic growths 1 patient was cured and in 1 the results were promising of 5 patients treated for unilateral cordal and subglottic cancer, 1 patient was cured and the results were promising in 3 of 32 patients with bilateral intrinsic laryngeal cancer 7 were cured and in 7 the results were promising.

Laryngofissure laryngectomy and irradiation with interstitial radium, radium collar radium beam and deep x ray therapy were the methods of treatment. The type of treatment was selected according to the site and extent of the tumor.

After his experience of 20 years the author suggests that growths limited to the membranous vocal cord are best treated by laryngofissure. A unilateral cord growth extending to the posterior arytenoid cartilage or the posterior commissure is treated by external irradiation or interstitial radium. A diffuse growth should be treated by total laryngectomy.

CLAUDE H. THURMAN, M.D.

Methylthiouracil in the Treatment of Thyrotoxicosis. ARNE BARRER. *Am J Med Sc.* 1947 214: 349.

The first group of patients to be treated with methylthiouracil had iodine resistant thyrotoxicosis and were given large doses of the drug (1 gm. or more a day). Forty-four per cent developed such severe toxic reactions that the drug had to be discontinued but 7 per cent were treated successfully.

The second group of patients treated with this drug had not received iodine to any extent before the administration of methylthiouracil. In this group smaller doses of the drug were used and the authors now believe that the dose should not exceed 0.4 gm. a day. There were 43 patients in this group. In 5 or 12 per cent, the treatment had to be stopped because of toxic reactions, and in 37 or 86 per cent, the treatment was considered to be effective. The dosage was gradually decreased and when the patient had done well for a month on 0.05 gm. a day the drug was completely withdrawn usually after an average period of 5 months.

Of the patients effectively treated with methylthiouracil 36.4 per cent maintained a sustained remission after withdrawal of the drug and were considered cured of their thyrotoxicosis, while 27.2 per cent suffered a remission after withdrawal of the drug. Thus, in starting methylthiouracil treatment only one-fourth of the patients may be expected to be cured. Some of the author's cases were apparently methylthiouracil resistant cases.

The author concludes that methylthiouracil is a more powerful antithyroid drug than thiouracil, but that the toxic reactions of the two drugs appear to be about equal. He believes that antithyroid drugs are contraindicated in large intrathoracic goiters in large goiters causing pressure symptoms, in noncooperative patients, in thyrotoxicosis which are due to acromegaly and possibly in thyrotoxicosis associated with pregnancy. He found that the test for urobilin in a 1 to 10 dilution of urine was a particularly sensitive one for early toxicity, thus confirming other reports that liver damage is often one of the earliest signs of toxicity.

Bell's Palsy: Pathology and Surgery; A Report Concerning 50 Patients Operated on by the Method of Ballance and Ducl. KARSTEN KETTEL. Arch. Otolaryng. Chic., 947 46 487

Since 1932 when Ballance and Ducl began operating on patients with Bell's palsy by opening and decompressing the fallopian canal from the stylomastoid foramen to the lateral semicircular canal investigation as to the etiology pathology and therapy of this disease has actively progressed. The present study is based on observations made in 50 operative patients, with consideration to the pathogenesis of the condition and the value of the decompression operation.

Previously the gross and microscopic pathology of the facial nerve and the surrounding region has revealed alterations of the axis cylinders and medullary sheaths, usually greater in the peripheral portions. Occasionally degenerative changes were noted in the facial nuclei. Inflammatory changes have been rare. A few authors have found distinct alterations in the cells of the mastoid process along the facial canal and others have described edema of the facial nerve in instances of recent paresis and atrophy in chronic cases.

In the series of cases here summarized extensive bony necrosis of the mastoid cells was observed in 11 patients (20 per cent). In 5 this involved the entire cellular system and had been noted roentgenologically whereas in 6 it was found only in the apex of the mastoid process, especially about the region of the stylomastoid foramen. Microscopically there was slight osteoporosis and bony necrosis. There was no suggestion of any inflammatory process. The facial canal was grossly soft in 18 patients (36%) while in all of the others it appeared normal. In 28 patients (56%) the nerve was unquestionably edematous grossly in 2 it was possibly atrophic and in 1 patient the changes were so marked that nerve continuity was interrupted. In this instance microscopic examination revealed nerve trunk edema, fibrinous exudation, fresh hemorrhage and marked degeneration of the axis cylinders and medullary sheaths. There were remnants of a venous thrombosis in the nerve sheath.

Previous authors have suggested that Bell's palsy is due to an inflammation (a latent nonsuppurative otitis media) or an aseptic disturbance of the blood supply. Numerous observations support the theory that the genesis of this disease is due to a disturbance of the vasa nervorum and this theory is held by the author on the basis of his pathological and clinical studies. In the majority of cases the nerve, as the most susceptible tissue suffers alone in others the surrounding more resistant bone is affected. The

result is ischemic paralysis and ischemic myocrosis. All symptoms and findings are then explained by ischemia of the facial nerve and the mastoid region. The rapidity of paralysis and its progress depends upon the vessel size, degree of ischemia, or re-establishment of the circulation.

Since previous experience has shown that the great majority (from 85 to 95%) of the cases respond to conservative treatment, the problem arises as to which patients to select for operative intervention. The faradic reaction has been used by previous investigators as a reliable index, but the author does not concur in this opinion. Cases are cited in which a negative faradic response was obtained but complete recovery took place later. The author gives indications for the surgical treatment of Bell's palsy.

1 A decompression should be done in cases in which signs of beginning mobility have not appeared after an observation period of 2 months.

(Of 25 patients operated upon, 30 were ready for re-examination. Two had recovered completely. No patient showed any weakness when the face was at rest and all of the patients could close the eye completely and smile, but to a varying degree.)

2 A decompression should be done if the spontaneous recovery of mobility has ceased before complete restitution has been obtained.

(Of 17 patients operated upon, 13 were ready for re-examination. Nine patients showed improved mobility and 1 patient had recovered completely. One obtained relief from a contracture which had formed before operation. In 3 patients the procedure was of no benefit.)

3 Decompression is indicated in relapsing paresis.

Of 8 patients in this group 5 recovered completely and the mobility increased in all. The beneficial effect of decompression of the facial nerve in cases of Bell's palsy is believed to be due to improvement of the blood flow by release of pressure on the vasa nervorum or by the establishment of a collateral circulation. C. FREDERICK KETTEL, M.D.

SPINAL CORD AND ITS COVERINGS

Relations of Nerve Roots to Abnormalities of Lumbar and Cervical Portions of the Spine. J. J. KEEGAN Arch. Surg. 947 55 445.

Results of careful neurological observations are presented on 1155 cases of compression, infection, or section of single posterior nerve roots. Of these, 1,030 were in the lower extremity 583 being relieved by surgical intervention. Ninety-eight were in the cervical region, and 31 of these were treated surgically.

It is postulated that loss of a single nerve root produces an area of hypalgesia, in contrast to the previously accepted dictum that such a loss causes no sensory disturbance.

If vertebrae are counted in total numerical sequence and not arbitrarily defining region. C-5... lumbar region as bordered by the last rib and the sacral segment no alteration in the segmental distribution of nerve roots is noted despite the addition or fusion of vertebrae. This method of terminology is recommended for describing the location of areas of disk. A new dermatome chart of the upper and lower extremities is given based on hypodermic patterns from loss of a single nerve root. This does not support the usual anatomic teaching of cutaneous variation and forward transmutation of nerve roots. A few areas in the developing limb buds of the trunk, when added to the usual dermatome chart of the trunk, it presents an orderly sequence of innervation of skin areas in direct numerical relation to the nerve roots. (See Fig. 1)

PERIPHERAL NERVES

Observations on the Treatment of Traumatic Injuries of the Peripheral Nerves. By ALVIN S. FRIEDLAND. *Bull. J. S. A.* 1941, 31, 37.

Two hundred and ninety-four patients with 330 peripheral nerve injuries incurred by war wound and related injuries were observed for periods up to 6 years. Unexpectedly favorable results were obtained by conservative treatment. This was improved by circumstances at first but was later pursued liberally.

Of the 330 patients recovered spontaneously 64 per cent, surgically 31 per cent were re-implanted. Of the last 1 per cent were subjected to radical amputation 6 per cent had damage beyond repair 16 per cent had some nerve tissue intact but subsequently recovered spontaneously. Let us due to projectiles showed a high incidence of spontaneous recovery. The incidence of paraplegia and injuries of the radial and ulnar nerves increased when the corresponding long line was in.

Three factors should all be considered as a catalyst in the treatment of peripheral nerve injury.

Degree of interruption of nerve conductance.

Duration of the latent period, the time required for the nerve to resume its function.

Appearance of the nerve at the site of injury.

The presence of neuroma or neuroma-like tissue.

Recovery of the nerve after the above factors have been considered.

It is apparent that the above factors are of great importance in the treatment of peripheral nerve injuries.

Fig. 1 (Keenan) Dermatome chart of the human body with new dermatome patterns of the extremities and the standard dermatome patterns of the trunk. Note the serial continuity of the dermatomes in the extremities and the trunk. (See p. 34 for abstract)

How Long Should an Extremity be Immobilized after Nerve Suture?

104-12-34

In the suture of a nerve, hands every nerve is with the use of various procedures of covering the gaps which result from the loss of substance of nerve or the retraction of their stumps. The method commonly used for gain length of the nerve is extensive freeing of the nerve, retaining it with the neurotony of the nerve. Even when these steps are taken it is sometimes necessary to introduce nerve grafts. It is the author's preference to the use of grafts, but that is not the line. In these instances, when the suture is not successful, the nerve is often anastomosed to a healthy nerve, usually the radial nerve. The period of immobilization is not too long, but it is not too short. It is the author's experience that the nerve should be immobilized for a period of 10 to 14 days. This is based on the fact that the nerve is not yet healed, but it is not too long to cause atrophy. The author's experience is that the nerve should be immobilized for a period of 10 to 14 days. This is based on the fact that the nerve is not yet healed, but it is not too long to cause atrophy. The author's experience is that the nerve should be immobilized for a period of 10 to 14 days. This is based on the fact that the nerve is not yet healed, but it is not too long to cause atrophy.

and then sutured by the use of the autologous plasma clot technique. Two of the 3 untwisted strands of No. 00 corticelli black silk were used as tension sutures to approximate the nerve ends, and accurate apposition was achieved with the aid of plasma clot. The animals were sacrificed at various intervals after operation, and 4 cm. segments of the nerve were removed (2 cm. to each side of the suture site). Also 4 cm. segments of intact sciatic nerve were excised. The silk tension sutures were removed and tensile strength measurements were made of the suture site, the intact nerve and of one of the withdrawn silk tension sutures from each nerve. For the purpose of microscopic study the same technique of nerve suture was used upon the sciatic nerves of dogs with the exception that tantalum wire (.003 inch in diameter) which causes less tissue reaction than silk, was used for tension sutures. Observations were made upon several hundred of such nerves at intervals ranging up to 18 months after operation. This material was prepared for study by a variety of histologic techniques.

The technique employed for the measurement of tensile strength was essentially that described by the author in a previous publication. Increasing increments of weights were applied until rupture of the nerve took place.

Histologic observations disclosed that a few monocytes and polymorphonuclear leucocytes appear within the plasma cuff as early as from 24 to 48 hours after nerve suture and an occasional fibroblast may be seen at this time. The fibroblasts increase in number and a normal epineurium is reconstructed from the plasma sheath in from 7 to 10 days.

As early as from 3 to 5 days after suture cells may be seen streaming across the suture line but occasionally signs of such cellular proliferation are strikingly absent. Sections taken 9 days after operation have shown structural continuity of schwannian and endoneural sheaths, although not uniformly in all cases. In practically all sutures 18 days or particularly 3 or more weeks old complete restoration of structural continuity has occurred. The growth of nerve fibers through the suture line may be demonstrated at this age.

Tensile strength determination confirmed that the suture site regained or even exceeded the strength of the intact sciatic nerve in 19, or more days after operation. The nerves appeared to achieve a greater tensile strength value at a certain time when their ends were accurately coapted and well joined. It appeared that the general condition of the animal too played a role in governing the rate of healing at the suture site. The microscopic observations in dogs indicate that this statement applied also to this species since structural continuity at the suture line was found to be complete at approximately this time. It seems justifiable then to advocate the removal of plaster of Paris encasements or other means of limb fixation 3 weeks after nerve suture and the institution of gradual extension of the joint at this time. There would be no danger of rupture of the suture

site in well made unions when a nerve is subjected to any strain 3 weeks after suturing. However, there is no doubt that there is a limit to which a nerve can be stretched and yet remain capable of recovery with resultant functional recovery of the severed part.

It is concluded that in those cases in which joints must be flexed in order to perform end-to-end union of nerves and the extremity encased in plaster, encasement may be removed 3 weeks later with danger of rupture of the suture site during its subsequent extension of the limb.

HOWARD H. LADD, M.D.

Rate of Regeneration of Sensory Nerve Fibers STURGEY SUNDERLAND. *Arch. Neurol. Psychiat.* 1947 58: 1

Although Tinel's sign has been frequently used in the estimation of rate of growth of peripheral nerves the reports have failed to specify or explain at what period of regeneration this sign has been investigated, or if repeated observations were made at varying intervals. The present report does not attempt to correlate the morphologic study of the regenerating nerve fiber with Tinel's sign, or to prognosticate the value of this sign.

The present study was derived from 11 guinea pigs with 12 peripheral nerve lesions. In 9 cases the suture was performed while in 3 cases the lesion was of the type defined as axonotmesis. It is concluded that nerve regeneration as evidenced by Tinel's sign does not progress at a steady rate but by a progressively diminishing rate. In the early stages (the first 100 days) there was a decline from 1.5 mm. per day (possibly 3 mm. in the very early phase) to 1 mm. per day. An intermediate stage of from 100 to 200 days revealed the growth rate at approximately 1 mm. per day. The terminal stage (from 200 to 300 days) showed a further definite drop from 0.8 to 0.5 mm. per day.

In a previous paper the author reported his study of the rate of regeneration of motor fibers by a completely different method from which it was assumed that the rate of growth was of functionally mature motor fibers. The fibers found in that group were very similar to the present group of sensory fibers, hence although the processes may not be similar there was no appreciable difference in the rates of advance of sensory or motor fibers as measured by dissimilar methods of investigation.

JACK I. WOOL, M.D.

SYMPATHETIC NERVES

Surgical Treatment of Hypertension. REEVES J. B. *Brit. Med. J.* 1947 45: 24

A report of the results obtained in 439 selected hypertensive patients treated by lumbar sympathectomy is made in this article. The possible causes of hypertension (increased peripheral resistance to the flow of blood through the arteries, in particular) are mentioned and the physiologic and

SURGERY OF THE NERVOUS SYSTEM

Regeneration after Sympathectomy and Its Effect on Raynaud's Disease. H. A. HAXTON *Brit J Surg* 1947 35 69.

genic mechanisms behind these theories are out of the operative exposure including a paravertebral division from the ninth rib to the iliac crest with removal of portions of the eleventh and twelfth ribs. The division of the diaphragm is described. This allows the removal of the sympathetic trunk from the eighth thoracic to the first lumbar ganglia in a dissection but may be extended down to the second and third lumbar ganglia if necessary. The greater splanchnic is reacted down to the celiac ganglion from the midthoracic region. The operation is bilateral, and is done in two stages. The operation is bilateral in length, and a descriptive study are outlined at different types of hypertension.

The results have been determined on the basis of the amount of drop noted in the diastolic pressure. Group 1 includes those cases in which there was a drop of 20 millimeters or more and to below 90 mm. Group 2 includes those cases in which the diastolic pressure is lowered 20 millimeters or more but not to below 90 mm. Group 3 includes patients whose diastolic pressure was lowered less than 20 millimeters or who showed no change at all. Group 4 includes patients in whom the diastolic level and pulse pressure were essentially unchanged but the ceiling levels were lowered. Patients in group 5 showed no change in blood pressure. Those in group 6 had higher blood pressures. Those in group 7 died. Patients in groups 1, 2, and 3 are believed to have been benefited.

The results obtained in the 439 unselected cases are as follows: 65.8 per cent of the patients are improved, the condition in 21.8 per cent of the patients is unchanged, 6.8 per cent of patients show a higher level of blood pressure. Death occurred in 14.6 per cent of the patients. The cases have been followed up for periods of from 1 to 5 years.

Further "selected" cases are described and the criteria for operation in the various groups are outlined in detail. The results following surgery in 329 selected cases were as follows: 84.8 per cent of the patients were benefited, 11.6 per cent were unchanged, 4.4 per cent had higher blood pressures, 17 per cent of the patients died.

HOWARD A. BROWN, M.D.

To ascertain the completeness of a sympathectomy the author favors the use of the skin electrical conductivity test. Sweating skin conducts electricity more readily than dry skin and therefore has a low resistance. After a sympathectomy the affected area a resistance increases a hundredfold. If one wishes to examine the skin electrical conductivity of the body generally it will be an aid to place the person in an environment which encourages sweating. To test the extremities, however, this is unnecessary because the palmar surface of the digits is usually moist and can be readily tested without inducing sweating. The author believes this test to be much more delicate than the digital skin temperature. Tests have been done following various types of sympathectomies and the following illustrates the degree of anhidrosis occurring after each.

Section of the cervical chain produces anhidrosis of the affected side of the face, neck and upper thorax to below the clavicle. This corresponds to the distribution of the fifth cranial nerve and the first three cervical dermatomes.

Section of the thoracic sympathetic chain at the level of the third rib and at the upper end of the chain with division of the rami from the second and third thoracic nerves produces anhidrosis in the upper limb and in the upper thorax. Following surgery the hand is dry and warm but the temperature gradually drops until it is a few degrees above the preoperative level. The removal of a 3 to 6 cm. segment at the third lumbar level produces anhidrosis of the foot and leg except for a small strip above the middle malleolus.

To study the results of these operations, tests were done on 46 upper and 38 lower extremities from 1 to 14 years after surgery. In all the extremities examined with the exception of 7 lower extremities, some return of sympathetic activity was demonstrated. The patients' stories indicated that 18 of the upper extremities and 4 of the lower extremities had a recurrence of pain. The author believes that the relapse is due to a regeneration of sympathetic fibers and local sensitivity of the vessels to cold.

DANIEL ROOS, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Surgical Management of Large Defects of the Thoracic Wall HERNLE C. MAIER. *Surgery* 1947 33 169.

Large defects in the thoracic wall may result from the radical resection of tumors, from areas of radiation necrosis and from trauma. Although the chest wall may be extensively involved by infection destruction of the entire thickness over a large area is uncommon. If the loss of tissue of the thoracic wall involves only the skin, subcutaneous tissues, and extrathoracic muscles, the principles of management are similar to those followed when treating defects in other portions of the body. When the bony or cartilaginous structures are destroyed or removed over a considerable area, problems peculiar to the thoracic cage are encountered. If the defect extends into the pleural cavity the problem of an open pneumothorax must be met.

The resection of several ribs, cartilages, or a large segment of the sternum deprives that portion of the chest wall of its normal stability and results in paradoxical motion. The degree of abnormal mobility on respiration will vary with the location and extent of the defect, and will also be influenced by the thickness of the soft tissues and other factors such as the presence of pulmonary emphysema. If the resection of the lesion of the chest wall requires the sacrifice of the parietal pleura, a flap of tissue must be made available for an airtight closure of the opening. Skin grafting alone would obviously be inadequate in such cases.

Local recurrence of carcinoma following radical mastectomy for cancer of the breast may merit surgical excision if there are no evident distant metastases. The value of such secondary operations is considerably enhanced if the procedure is of a radical type. Often the entire thickness of the thoracic wall from the skin to and including, the parietal pleura should be excised. If the surgeon compromises in the extent of the excision in order to avoid a large defect or opening into the pleura, less satisfactory results will be obtained. When the resection includes the cartilages, ribs, intercostal structures and parietal pleura, a flap of skin and subcutaneous tissues down to the deep fascia should be mobilized from adjacent areas and swung over the defect as a pedicle flap. Since the tissues in the region of the previous mastectomy wound are rather fixed and somewhat fibrotic, this pedicle flap should be fashioned from tissue which was not in the field of the original mastectomy operation. A flap for the central part of the thoracic wall may be obtained by mobilizing the tissues forming the medial portion of the opposite breast.

By completely mobilizing the breast on the opposite side at its lower margin and to a considerable

extent along both the axillary and medial ends, the breast can be displaced considerably and maintain an excellent blood supply through its upper and axillary attachment. The defect closed by the displacement of the breast toward the opposite side of the anterior chest wall can usually be closed without tension by mobilization of the subcutaneous tissue in the lower axillary and upper abdominal areas. An additional incision may be required to permit a satisfactory advancement of the latter flaps.

The tissue of the anterior abdominal wall, the pedicle laterally, may be utilized for defects in the lower anterior thoracic region, and pedicle flaps from the axillary region may be used for the closure of defects in the lateral portion of the thoracic wall. If intensive radiation therapy followed the radical mastectomy the situation is more complicated.

Resection of a tumor of the chest wall often requires removal of the ribs, intercostal structures, and parietal pleura en masse over a considerable area.

Any repair of the thoracic wall which does not employ bony structures or periosteum from rib bone can regenerate fails to give an ideal result. Permanent paradoxical motion with respiratory bulging on coughing or straining may be avoided. Therefore, whenever possible periosteum or segments of rib or cartilage should be used in the closure of the defect. The employment of a foreign body such as tantalum plate has been satisfactory but cause proper anchorage and imbedding has proved feasible. It is difficult to immobilize a metal plate in a moving chest wall.

The most satisfactory repair of average size defects was obtained by using a periosteal flap developed from ribs immediately above and below the margin of the hernial orifice. In some cases ribs at the margin of the defect were cut tangentially and then displaced upward or downward and fixed to the rib stump of an adjacent partly resected rib. The displaced ribs helped to narrow the defect, and the periosteum from these ribs could be returned to its another to further lessen the space. These measures, however, could not be employed in some of the large defects that were encountered, and in such cases a closure which does not have the stability of the normal thoracic cage was obtained. If a large defect of the entire thickness of the thoracic wall was present, combined with an emphysema, a combination of thoracoplasty and the use of a full thickness flap of the chest wall was employed. A defect over the precordium was closed by making an intercostal incision through the full thickness of the chest wall lateral to the defect at its upper and lower margins. Because the paravertebral portion of the ribs of this area had previously been removed subperiosteally it was possible to slide this full thickness flap

the precordium and hold it in place by sutures. Because such a flap contains pericardium, later bone regeneration can occur and the chest wall may become firm in contrast to the flaccid chest wall when only a flap of soft tissue is employed.

Sexual Alteration of Advanced Cancer of the Breast. IKA T. NATHANSON, *Surg Clin N Amer*, 1947 27 1144

Evidence is presented showing the relation and effect of hormones on cancer of the breast. Successful responses have been obtained following gonadal therapy on the soft tissue manifestations of cancer primarily in elderly women. Androgen therapy on the other hand may favorably influence metastases in women of any age. Castration of most manifestations in premenopausal women gives responses are only temporary as reaction is the rule.

The administration of sex hormones or castration in carefully selected patients may be of value as a palliative measure when other methods are not feasible or as an adjunct to the orthodox procedures. The studies indicate that breast cancer may be dependent upon the endocrine status of the host. It appears therefore that the validity of the classic concept of autonomy of cancer cells must be questioned. The fact that alterations occur in breast cancer following sex hormonal administration or deprivation should lead to intensive investigation regarding the mechanism involved. If this is kept foremost in mind rather than the possibility that hormones may be a means of cancer therapy progress can be expected.

TRACHEA, LUNGS, AND PLEURA

A Study of Variations of the Bronchopulmonary Segments in the Left Upper Lobe. J. GORDON S. JONES, *J Thorac Surg* 1947 6 539

The left upper lobe bronchus usually bifurcates into a superior and an inferior (lingular) division (Fig 1). The upper division then divides into an anterior (B¹) and an apical posterior segmental bronchus (B² and B³). The anterior segmental bronchus (B¹) which reaches the interlobar fissure and adjacent costal surface and an anterior ramus (B⁴) which supplies the more anterior costal and mediastinal surfaces into an apical subsegmental bronchus (B⁵) and a posterior subsegmental bronchus (B⁶). The lingular inferior (B⁷) segmental bronchus. The principal variation in the left upper lobe centers about the development of an accessory anterior bronchus (B⁸), which is usually accompanied by a downward displacement of the anterior segmental bronchus (B¹) so that a pattern approaching trifurcation of the left upper lobe bronchus is

Fig 1 (Scannell). Injected specimen (No. 1) demonstrating prevailing pattern in series described by Lloyd and Hartmann. Costal surface on left, mediastinal view on right. B¹ failed to fill with the injection mass and is indicated by an asterisk. C = sternum (or lingular crest). C' = posterior crest. C'' = subclavian crest.

Fig 2. Injected specimen (No. 18) depicting trifurcate branching of upper lobe bronchus caused by downward displacement of anterior segmental bronchus, B¹, which then forms central limb of trifurcation an accessory segment, B⁸. Superior lingular bronchus, B⁷, is incomplete since its posterior ramus is absent and it lacks representation on costal surface B and B¹ were not injected separately in this specimen.

presented (Fig 4). Variations in composition of the anterior area of the left upper lobe are centered about the posterior ramus of the anterior segmental bronchus (B¹). This posterior ramus is often absent and the defect is remedied by compensatory expansion of the adjacent subsegments (B² and B³) or by the appearance of an accessory branch (B⁸). In the majority of instances of an absent B¹, the lingular segment (B⁷) supply the area involved. In the series of 13 specimens studied, only one showed a posterior segment (B⁷) extending upward to include the highest point of the lung. However, if the apex be considered as that portion of the lung lying above the plane of the first rib then 4 of the 13 specimens showed the posterior segment entering into the apex.

Intralobar Sequestration of the Lung Associated with an Abnormal Pulmonary Artery. D. M. FRY, T. HOLMES SELLERS, and L. G. BLAIR, *B J Surg* 1947 55 18. This article describes certain abnormalities in the vascular supply and anatomy of the lung which the

SAMUEL KALIN M D

surgeon may encounter at operation. Three types may be recognized (1) abnormal artery to the normally connected lung, (2) abnormal artery to a sequestered mass and adjacent normal lung, and (3) abnormal artery confined to the sequestered mass.

In spite of their origin from the aorta, these abnormal arteries are not bronchial arteries. Bronchial arteries are small and muscular but these vessels are large and have the elastic structure characteristic of pulmonary arteries. As the result of the higher blood pressure, these abnormal pulmonary arteries often show atherosclerotic changes.

The sequestration appears as a large cyst—a mass of polycystic lung connected with a dislocated blind bronchus at the hilum or a mass of lung with bronchi branching parallel with the abnormal artery.

Inflammatory changes occur and vary greatly and the clinical symptoms are all referable to infection which usually began early in life.

Diagnosis is difficult and usually a neoplasm is suspected. Roentgenography is of practical help.

The condition may be recognized at operation, which is usually undertaken for supposed bronchiectasis, cystic disease or empyema. Occasionally the condition is only identified on pathologic examination. Surgical excision is the appropriate treatment in view of the tendency toward infection.

The abnormality is obviously related to a lower accessory lung which may come from an extra lung bed or is a detached part of the developing lung. The sequestration may be complete or partial. The condition shows a preponderant tendency to occur on the left side, probably being associated with the bulging of the heart to that side.

The authors report 8 cases, narrating the history and course of this complex congenital condition.

STEPHEN A. ZIPMAN, M.D.

Experience with Thoracic and Thoracoabdominal Wounds in an Evacuation Hospital. S. A. MACLELLAN. *J. Thorac. Surg.* 947 6 33A.

Patients with wounds of the chest may be divided into 2 groups: those that require thoracotomy and those that do not. Of 285 patients with penetrating and perforating wounds of the thorax, 65 required thoracotomy. The indications for thoracotomy in the order of frequency with which they occurred are: (1) the anatomic likelihood of diaphragmatic penetration, (2) the presence of large intrapleural and intrapleural foreign bodies, (3) the presence of missiles in or traversing the mediastinum, (4) wounds of the large bronchi, and (5) continuing intrapleural hemorrhage.

Thirty-five of the 65 patients in whom thoracotomy was done required in addition exploration of the peritoneal cavity through the diaphragm. There were 5 deaths in this group of 65 patients—a mortality of 7.7 per cent.

Two hundred and twenty patients did not require thoracotomy. The general management of these wounds consisted of débridement, the prevention of

sucking by suturing the breach in the thoracic wall, and the evacuation of blood and air from the pleural cavity to obtain early expansion of the lung. Ten of these patients died, a mortality of 4.5 per cent.

Preoperative and postoperative care was directed toward the achievement of three basic aims: the restoration of respiratory equilibrium, the restoration of circulatory equilibrium, and the prevention of infection.

Respiratory distress was corrected by the maintenance of a clear tracheobronchial tree and by expansion of the lung by repeated thoracocentesis whenever necessary. The use of oxygen as an adjunct in the treatment was routine.

Circulatory imbalance was treated by the administration of citrated whole blood in an amount sufficient to give an adequate response. It was not unusual to administer from 1,000 to 1,500 cubic centimeters.

The factor of greatest importance in the prevention of infection during the postoperative period was the early obliteration of the pleural space by an expanded lung. This was achieved by repeated thoracocentesis. Penicillin was given intramuscularly in the amount of 25,000 units every 3 hours. This was begun on admission and continued until the lung was completely expanded.

SAMUEL KARR, M.D.

Traumatic Rupture of the Bronchus. THOMAS J. KIDWELL and L. W. JOHNSON. *J. Thorac. Surg.* 947 6 571.

Traumatic rupture of the bronchus occurs very rarely and is recognized clinically with even less frequency. At least 38 cases have been reported in the literature and 3 cases are added by the authors. The history in most cases is the same. The patients sustain a severe chest injury of a compression or crushing type; the ribs may not be fractured, and hemoptysis may not occur. Shock is usually profound. Marked dyspnea and cyanosis may develop if a tension pneumothorax occurs; hemothorax and subcutaneous emphysema may appear. The condition occurs at all ages, usually in males.

The exact mechanism by which the lesion occurs is not always clear. Apparently a severe shearing force is brought to bear upon the bronchus, causing it to rupture. The point most likely to tear is the main bronchus, within a few centimeters of the trachea. The right and left sides are involved with equal frequency. Rupture of the lung itself is not usually found in association with rupture of a bronchus, nor are the arteries and veins of the pulmonary hilum injured as often as would be expected.

Following the bronchial tear a pneumothorax of varying extent develops in about 40 per cent of all cases. Complete or nearly complete bronchial occlusion occurs with the development of a marked atelectasis of the involved lung, followed by an extremely marked shift of the heart and mediastinum toward the affected side, producing the dyspnea, chest discomfort, and other symptoms of which the patient is subsequently complain. If the obstruction

is not complete secondary bronchiectasis and inflammatory changes are likely to ensue.

The first therapeutic considerations should be the administration of oxygen to correct the anoxemia the administration of blood and plasma to combat shock and hemorrhage the aspiration of air from the pneumothorax side to relieve intrathoracic tension and incision if necessary, to relieve tension from mediastinal emphysema. If rib fractures are present sedatives or novocain block may be found of distinct value.

Early bronchoscopy should be done if the patient's condition permits it. If blood clots are present they should be removed in order to relieve atelectasis.

The condition may be amenable to surgical treatment. The risk of exploration may be slight as compared to the risk of doing nothing. The suture of an incompletely torn bronchus at the site most often affected should not prove to be too difficult. Even suture of a complete rupture of the bronchus, with the pulmonary and bronchial vessels intact, may also be possible. If a stricture results and the entire lung becomes atelectatic, a therapeutic pneumothorax on the affected side may relieve the symptoms and hold the mediastinal structures at or near the midline.

Patients who have an incomplete bronchial obstruction with infection will eventually develop bronchiectasis and infection in the lung distal to the stenosis. In such cases, pulmonary resection should be considered. Mediastinal shift, and overexpansion of the contralateral lung will be less following total pneumonectomy than from the atelectasis due to the bronchial stenosis as the fluid and coagulum which fill the pleural space after pneumonectomy occupy more space than the atelectatic lung which has been removed.

SAMUEL KAHN, M.D.

Pneumonectomy for Chronic Suppurative Emphysema (Neumonectomia por sepsis cronica del pulmon). JUAN C. BIDART, MALINER and JOSE GALARCE. *Bol. Acad. argent. cir.*, 1947 31 373

This article is principally a report of a chronic non-tuberculous lung abscess treated successfully by pneumonectomy. It occurred in a 39 year old male, who gave a 6 months history of the disease and had failed to respond to conservative management.

An excavating neoplasm was suspected of course and thoracotomy carried out. The gross findings at operation were compatible with neoplasm and a pneumonectomy by individual ligation technique was performed.

The postoperative course in this case was complicated by extensive breakdown of the wound in the chest wall as a result of infection. It is anticipated that a thoracoplasty will be performed. No neoplasm was found in the resected specimen. There was instead a suppurative process containing a well defined abscess cavity.

The justification for resection in chronic pulmonary suppuration is briefly discussed.

HIRSH T. LAROSTOM, M.D.

Pulmonary Cysts, with Special Reference to Surgical Treatment of Emphysematous Blebs and Bullae. ENRIK NACLERIO and LAZARO LANORA. *Surgery* 1947 22 516

Although the precise mechanism of the genesis of pulmonary cysts is unknown. It is believed that they originate from some developmental anomaly. There are three probable origins: congenital bronchiectasis, dilatation of lymphangiomatous spaces, and aberrant lung tissue or vestigial structures.

The manner in which a bleb is formed is similar to that in which interstitial emphysema occurs. There is a rupture of the wall of an alveolus which allows air to escape into the alveolar layer of the pleura.

In the case of bullae the alveoli are first dilated then atrophy and rupture of the alveolar wall occur. Various sized bullae gradually form which communicate with a bronchiole or a larger division of the bronchial tree. When blebs are present, the pleura is separated by the air from the underlying alveolar walls. When bullae occur the pleura retains its connection with the lung although the alveoli beneath them produce the bullae through rupture and fusion. The bullae can be considered best as an advanced stage of a localized pulmonary emphysema.

Since blebs and bullae are often associated with marked emphysema the clinical picture may be that of the latter condition only. The symptoms depend on the size, location, valvular mechanism, and condition of the contiguous lung parenchyma, and changes that may occur in the intrathoracic pressure. Infection is rarely seen in blebs and bullae although cysts of other types are prone to infection and produce symptoms of pulmonary suppuration. Blebs and bullae may remain symptomless for long periods and become distressing only when they are very large. Dyspnea may then become a prominent symptom and cough, expectoration and pain in the chest may appear. Occasionally a spontaneous pneumothorax may result from the rupture of a bleb or bulla.

Pulmonary blebs and bullae, even when large may be asymptomatic, and may be discovered only on x ray examination. They often disappear spontaneously. When severe and incapacitating respiratory symptoms appear operative procedure may be necessary.

Ten cases are reported: 5 of pulmonary emphysematous cysts, 3 of bullae, 1 of bleb and 1 of chronic interstitial emphysema involving the entire left lower lobe and the surgical procedure used in excising the involved area is described.

SAMUEL KAHN, M.D.

Malignant Lymphoma of the Lung and Pulmonary Coccidioidomycosis. EDWARD D. CHURCHILL. *Surg. Clin. N. America* 1947 27 1113.

Churchill reports a successful operative case of malignant lymphoma of the lung in a 45 year-old woman whose only complaint was aching pains in the right shoulder for over 20 years. Objective symptoms revealed little, and only after careful x ray

studies was the lesion in the upper right lobe of the lung considered operative. Because the middle lobe was fused with the upper lobe the two parts were removed after separate ligation and division of the hilar structures.

Röntgen therapy was instituted early. The patient made an uneventful recovery and is living with no evidence of the disease 6 months after operation.

A second case discussed was that of a 14 year-old boy with a baffling lesion in the upper left chest. After conservative methods failed surgery was undertaken. An immediate frozen section revealed a chronic inflammation probably coccidioidomycosis. The entire left lung with exception of the lingula was removed. After operation coccidioides were found in the sputum previously they had had no free access to the bronchus as the whole upper lobe on pathologic sectioning showed consolidation with only a few lung markings remaining.

STEPHEN A. ZIDMAN, M.D.

Primary Cancer of the Lung. ALTON OCHSNER, MICHAEL DEBAKEY and J. LEONARD DIXON. *J. Am. M. Ass.* 9:17 135 3

Within the past few decades two well established and generally accepted concepts of primary cancer of the lung have been completely disproved. One is the concept that carcinoma of the lung represents the rarest form of cancer. It now appears that lung cancer is one of the most frequently encountered neoplasms, being preceded only by cancer of the stomach. The other and more important concept disproved is that pulmonary cancer is a hopeless condition.

This is a review of 412 cases of cancer of the lung observed at Tulane University School of Medicine service in the Charity Hospital of Louisiana at New Orleans and in private practice at the Ochsner Clinic over a period of approximately 13 years. Of the 412 patients 246 underwent surgical exploration and of the 246 147 were subjected to primary pulmonary resection. An analysis of the experience with these patients with particular emphasis on the follow-up study on all patients who were submitted to primary resection is given. (This is essentially the same data, with 18 added resected cases, as that presented by Ochsner, DeBakey and Dixon in the *Annals of Surgery* (1947 185 538) and abstracted in *INTERNATIONAL ABSTRACTS* (1947 85 459).

Thirteen and six tenths per cent of the cancers occurred in women and 86.4 per cent in men. The fifth, sixth, and seventh decades were the most frequent time of appearance of the carcinoma. The etiology is obscure and both occupation and smoking previously particularly emphasized, were found to have no special significance in this analysis.

The most common early symptom is cough which is significant when any change in type of cough occurs and the change persists, particularly over a period of more than 3 or 4 weeks. Physical observations are extremely variable and depend upon the location of the carcinoma.

The most important factor in diagnosis is the consideration of the possible presence of cancer. Primary cancer of the bronchus should be suspected in every person over 40 years of age who has unexplained thoracic discomfort, a persistent cough, or hemoptysis. This is the key to increasing early diagnosis. Abscesses of the lung which cannot be satisfactorily explained in any man past 40 should be considered carcinoma until disproved. (The diagnosis of pulmonary abscess was the most frequent error encountered—5.4%.)

Röntgenographic examination is accurate initially in 83.5 per cent of the cases. Bronchoscopic examination with biopsy is the most accurate with positive diagnoses in 81.4 per cent of 74 cases in which biopsy was obtained among the 125 cases subjected to bronchoscopy. Thus a positive diagnosis was obtained by bronchoscopic biopsy in 41.5 per cent of 147 cases.

The lesion is located in the upper lobe in 49 per cent of the cases. Cytologic examination is particularly adapted to the verification of tumors in this location. Aspiration biopsy is condemned on the basis that implantation may occur along the site of the aspirating needle and thus preclude cure of the carcinoma. Exploratory operation should always be carried out for any unexplained thoracic complaint in a man past 40 years of age in whom the existence of bronchogenic neoplasm cannot be otherwise disproved or verified.

Extirpation of the tumor offers the only chance of cure. Pneumonectomy is the procedure of choice. The anterior approach is preferred.

The data indicate that for every 3 cases of pulmonary cancer 2 will appear to be operable and only 1 case will prove to be resectable. Both operability and survival rates are improving when statistics made prior to 1942 are compared with those made after 1942. The hospital mortality prior to 1942 was 46.4 per cent. It is now 19.3 per cent. Hospitalization has decreased from 32.3 days prior to 1942 to 13.5 days since 1942. Cardiovascular lesions account for 47 per cent of the hospital fatalities.

Survival rates drop rather rapidly within the first 3 postoperative years but by the third year become stabilized and continue almost as a plateau until the fifth year. This means that the five year survival of approximately one-fourth of the patients (23.5%) is approximately that of the 3 year survival rate.

A summary of operability and survival rates for all carcinomas of the lung according to these statistics would mean that 60 per cent of the patients meet the criteria for operability, 36 per cent could prove resectable, 18 per cent would survive the operation and 8 per cent would survive 5 years or longer.

The need for earlier diagnosis is readily seen if one reflects that should all cases be resectable when first seen then on the basis of present performance 50 per cent of the patients with carcinoma of the lung might be expected to survive 5 years or longer.

FRANK B. QUINN, M.D.

Induction of Bronchogenic Carcinomas in Mice.
E. S. HORMING. *Lancet* Lond., 1947 2 307

The author presents a preliminary report in which he describes the technique of inducing tumors by the direct application of carcinogenic compounds sometimes in combination with synthetic hormones, to adult lung tissue growing as homologous grafts in host animals.

Small pieces of adult lung are isolated under a dissecting microscope and impregnated with a few crystals of 30-methylcholanthrene. On placing the carcinogen in direct contact with the tissue to be grafted care is taken to wrap the tissue around the crystals so that they are shielded from contact with the tissues of the host. The grafts are implanted subcutaneously with a Bashford transplanting needle on each side of the belly of the host. As many as six subcutaneous primary grafts have been made in a single mouse. In all cases the graft tissue was taken from mice aged 3 months, belonging to the same strain as the hosts in which the grafts were to be implanted.

The host mice, bearing lung grafts, were mice of strains A and C3H which received lung implants impregnated with methylcholanthrene and were killed after an interval of 6 to 8 weeks, before malignant tumors had developed. The grafts were fixed for histologic study of early phases of carcinogenesis.

The pulmonary tumors were induced in both male and female mice, the incidence being about equal in the two sexes. The malignancy of the tumors was proved in all cases by transplanting portions of the primary tumor into mice of the same strain. All the transplants grew and some of these tumors are now in the third and fourth generations of transplantation. Grafts which did not develop tumors had become necrotic, presumably because of failure of vascularization.

In mice of strain C3H the tumor incidence was increased if the lung grafts were impregnated with stilbestrol in addition to the carcinogen.

The several advantages in this method of tumor induction are that the carcinogen is placed in direct contact with the living cells of the graft without the use of a solvent, and therefore there is little or no foreign body reaction or residue of necrosis, which might mask or conceal areas in which neoplastic changes first arise. Since the focus of activity of the carcinogen is within a graft and not in some part of a large organ the growth of the affected tissues may be more readily observed macroscopically and more easily removed for histologic examination of the early stages. The neoplasms arise in subcutaneous grafts and are maintained by subcutaneous transplantation. A series of grafts established in one host can be regarded as growing under identical hormonal conditions.

STEPHEN A. ZICKMAN M.D.

Bronchogenic Carcinoma. VIKTOR OLOV BJÖRK
Acta chir scand 1947 95 Supp. 123.

The author presents an admirable summary of facts obtained from an analysis of 345 cases of clin-

ically diagnosed bronchogenic carcinoma. The patients were treated at the Brompton Hospital for Diseases of the Chest and at the Royal Cancer Hospital (Free) in London during the period from 1937 to 1946.

The clinical findings were as follows: 90 per cent of patients were males and 10 per cent were females; 98.3 per cent of the patients were 30 years of age or over; 87.8 per cent were 40 years or over; the peak being from 50 to 54 years; 58.8 per cent of the lesions were located in the upper lobe and 38.4 per cent in the lower lobe. In 53 per cent of the cases there was a slight right predominance which corresponds to the normal values of weight and volume determination in which the right lung represents from 53 to 54 per cent. Pathological analyses were: squamous cell carcinoma 50.2 per cent; oat cell carcinoma, 14 per cent; undifferentiated carcinoma, 15.7 per cent; adenocarcinoma 9.2 per cent; and mixed adenocarcinoma and squamous cell carcinoma 9.9 per cent.

The anatomic classification of these tumors is as follows: central tumors, 65 per cent; intermediate tumors, 23 per cent; peripheral tumors, 12 per cent. No relation was observed between the histology and (a) localization, (b) duration of symptoms, (c) time of appearance of metastases or method of spread.

In women a relative predominance of adenocarcinoma (25%) was observed as compared to a 9.2 per cent incidence of all bronchogenic cancers in both men and women.

The most important symptom was a dry persistent cough lasting for a period of more than 4 weeks. Hemoptysis or pain both relatively late symptoms bring the patient to the doctor.

The methods of diagnosis were as follows: biopsy by bronchoscopy was done in 59 per cent of the cases; thoracotomy was carried out in 17 per cent; lymph node biopsy in 10 per cent; autopsy in 6 per cent; examination of sputum in 4.7 per cent of the cases; miscellaneous methods were used in 3.4 per cent. A total of 7.5 per cent of the tumors were operable (operability has been increased to 13.5 per cent since 1944). Operation could be completed in 49 per cent of the patients on whom thoracotomy was performed. Widening of the carina is not considered a contraindication to exploration since this may be occasioned by inflammatory enlargement of the lymph nodes at the bifurcation and may not be due to metastases. Only 21 per cent of enlarged hilar nodes were due to metastases; 79 per cent were purely inflammatory. Pneumonectomy with use of the dissection technique and closure of the bronchus by one row of isolated subterminal linen sutures and one continuous linen suture with a pleural flap is the operation of choice except in rare instances in which lobectomy is desirable for palliative reasons. Chemotherapy is used 2 days before and 1 week after operation. Preoperative pneumothorax is not useful.

In the present series the hospital mortality was 30 per cent. The primary mortality following the last 25 pneumonectomies was 8 per cent.

studies was the lesion in the upper right lobe of the lung considered operative. Because the middle lobe was fused with the upper lobe the two parts were removed after separate ligation and division of the hilar structures.

Röntgen therapy was instituted early. The patient made an uneventful recovery and is living with no evidence of the disease 6 months after operation.

A second case discussed was that of a 14 year-old boy with a baffling lesion in the upper left chest. After conservative methods failed surgery was undertaken. An immediate frozen section revealed a chronic inflammation probably coccidioidomycosis. The entire left lung with exception of the lingula was removed. After operation coccidioides were found in the sputum previously they had had no free access to the bronchus as the whole upper lobe on pathologic sectioning showed consolidation with only a few lung markings remaining.

STEPHEN A. ZIEGLER, M.D.

Primary Cancer of the Lung. ALTON OCHSNER, MI
CHARL DEBAKEY and J. LEONARD DIXON. *J. Am. M. A.*
1947 947 35 3

Within the past few decades two well established and generally accepted concepts of primary cancer of the lung have been completely disproved. One is the concept that carcinoma of the lung represents the rarest form of cancer. It now appears that lung cancer is no of the most frequently encountered neoplasms being preceded only by cancer of the stomach. The other and more important concept disproved is that pulmonary cancer is a hopeless condition.

It is now 19.3 per cent. Hospitalization has decreased from 32.3 days prior to 1942 to 13.5 days since 1942. Cardiovascular lesions account for 47 per cent of the hospital fatalities.

Survival rates drop rather rapidly within the first 3 postoperative years but by the third year become stabilized and continue almost as a plateau until the fifth year. This means that the five year survival of approximately one fourth of the patients (23.5%) is approximately that of the 3 year survival rate.

A summary of operability and survival rates for all carcinomas of the lung according to these statistics would mean that 60 per cent of the patients meet the criteria for operability 36 per cent would prove resectable 18 per cent would survive the operation and 8 per cent would survive 5 years or longer.

The need for earlier diagnosis is readily seen if one reflects that should all cases be resectable when first seen, then on the basis of present performance 20 per cent of the patients with carcinoma of the lung might be expected to survive 5 years or longer.

FRANK B. QUEEN, M.D.

Induction of Bronchogenic Carcinomas in Mice.
E. S. HORMING. *Lancet* Lond. 1947 2 307

The author presents a preliminary report in which he describes the technique of inducing tumors by the direct application of carcinogenic compounds sometimes in combination with synthetic hormones to adult lung tissue growing as homologous grafts in host animals.

Small pieces of adult lung are isolated under a dissecting microscope and impregnated with a few crystals of 30-methylcholanthrene. On placing the carcinogen in direct contact with the tissue to be grafted care is taken to wrap the tissue around the crystals so that they are shielded from contact with the tissues of the host. The grafts are implanted subcutaneously with a Bashford transplanting needle, on each side of the belly of the host. As many as six subcutaneous primary grafts have been made in a single mouse. In all cases the graft tissue was taken from mice, aged 3 months, belonging to the same strain as the hosts in which the grafts were to be implanted.

The host mice, bearing lung grafts, were mice of strains A and C3H which received lung implants impregnated with methylcholanthrene and were killed after an interval of 6 to 8 weeks, before malignant tumors had developed. The grafts were fixed for histologic study of early phases of carcinogenesis.

The pulmonary tumors were induced in both male and female mice, the incidence being about equal in the two sexes. The malignancy of the tumors was proved in all cases by transplanting portions of the primary tumor into mice of the same strain. All the transplants grew and some of these tumors are now in the third and fourth generations of transplantation. Grafts which did not develop tumors had become necrotic, presumably because of failure of vascularization.

In mice of strain C3H the tumor incidence was increased if the lung grafts were impregnated with stilbestrol in addition to the carcinogen.

The several advantages in this method of tumor induction are that the carcinogen is placed in direct contact with the living cells of the graft, without the use of a solvent, and therefore there is little or no foreign body reaction or residue of necrosis which might mask or conceal areas in which neoplastic changes first arise. Since the focus of activity of the carcinogen is within a graft and not in some part of a large organ the growth of the affected tissues may be more readily observed macroscopically and more easily removed for histologic examination of the early stages. The neoplasms arise in subcutaneous grafts and are maintained by subcutaneous transplantation. A series of grafts established in one host can be regarded as growing under identical hormonal conditions.

STEPHEN A. ZIEGLER M.D.

Bronchogenic Carcinoma. VIKTOR OLOV BJORX
Acta chir scand 1947 95 Supp. 123.

The author presents an admirable summary of facts obtained from an analysis of 345 cases of clin-

ically diagnosed bronchogenic carcinoma. The patients were treated at the Brompton Hospital for Diseases of the Chest and at the Royal Cancer Hospital (Free) in London during the period from 1937 to 1946.

The clinical findings were as follows: 90 per cent of patients were males and 10 per cent were females; 98.3 per cent of the patients were 30 years of age or over; 87.8 per cent were 40 years or over; the peak being from 50 to 54 years; 58.8 per cent of the lesions were located in the upper lobe and 38.4 per cent in the lower lobe. In 53.2 per cent of the cases there was a slight right predominance which corresponds to the normal values of weight and volume determination in which the right lung represents from 53 to 54 per cent. Pathological analyses were: squamous cell carcinoma 50.2 per cent; oat cell carcinoma 24 per cent; undifferentiated carcinoma 15.7 per cent; adenocarcinoma 9.2 per cent; and mixed adenocarcinoma and squamous cell carcinoma 0.9 per cent.

The anatomic classification of these tumors is as follows: central tumors, 65 per cent; intermediate tumors, 23 per cent; peripheral tumors, 12 per cent. No relation was observed between the histology and (a) localization (b) duration of symptoms (c) time of appearance of metastases or method of spread.

In women a relative predominance of adenocarcinoma (25%) was observed as compared to a 9.2 per cent incidence of all bronchogenic cancers in both men and women.

The most important symptom was a dry persistent cough lasting for a period of more than 4 weeks. Hemoptysis or pain both relatively late symptoms bring the patient to the doctor.

The methods of diagnosis were as follows: biopsy by bronchoscopy was done in 59 per cent of the cases; thoracotomy was carried out in 17 per cent; lymph node biopsy in 10 per cent; autopsy in 6 per cent; examination of sputum in 4.7 per cent of the cases; miscellaneous methods were used in 3.4 per cent. A total of 7.5 per cent of the tumors were operable (operability has been increased to 13.5 per cent since 1944). Operation could be completed in 49 per cent of the patients on whom thoracotomy was performed. Widening of the carina is not considered a contra-indication to exploration since this may be occasioned by inflammatory enlargement of the lymph nodes at the bifurcation and may not be due to metastases. Only 21 per cent of enlarged hilar nodes were due to metastases; 79 per cent were purely inflammatory. Pneumonectomy with use of the dissection technique and closure of the bronchus by one row of isolated subterminal linen sutures and one continuous linen suture with a pleural flap is the operation of choice except in rare instances in which lobectomy is desirable for palliative reasons. Chemotherapy is used 2 days before and 1 week after operation. Pre-operative pneumothorax is not useful.

In the present series the hospital mortality was 30 per cent. The primary mortality following the last 25 pneumonectomies was 8 per cent.

Of all patients operated upon and followed up (79) 5 per cent are alive longer than 5 years, 16 per cent are alive longer than 3 years, 23 per cent, longer than 2 years, 39 per cent longer than 1 year. The histologic differentiation of the cancer has no influence upon survival.

All inoperable tumors without contraindication should be treated by deep x rays. One 5 year survival has thus been secured. Untreated patients with carcinoma of the lung do not survive longer than 1 year after diagnosis. Contraindications to deep x ray treatment consist of poor general condition, extrathoracic metastases, large (but not small) pleural effusions, and well defined rounded tumor.

Postoperative deep x ray therapy is of value only in cases in which it is possible to exactly localise the area for treatment.

Deep therapy consists of 4,000 roentgens, or more, delivered through multiple small x ray fields applied from two opposing parallel planes on either side of the thorax with 4 fields applied to each plane each day, the position of the field being changed to an intermediate position on alternate days. By this means 250 per cent to 300 per cent of the dose given to any point of the skin may be delivered to the bronchial carcinoma. Ninety-two patients were so treated (excluding those in stage 4 with extrathoracic metastases). Complete relief of symptoms was obtained in 11 per cent, there was improvement in 46 per cent, no change in 19 per cent, and the condition became worse in 24 per cent.

This article contains the best factual summation of information on pulmonary carcinoma which this reviewer has encountered to date.

FRANK B. QUEEN, M.D.

Pulmonary Function after Pneumonectomy and Lobectomy. G. BRATHE, C. CRAWFORD, and P. RUDSTAM. *J. Thorac. Surg.* 1947 6 49.

Following pneumonectomy the total lung volume is somewhat less reduced than would be expected from the corresponding loss of parenchyma. In the position of maximum inspiration the remaining lung tissue is, therefore, exposed to increased distension. The distension of the lung tissue is especially marked in the respiratory midposition for in the equilibrium position the lung volume is approximately 50 per cent greater after pneumonectomy than can be expected from calculation.

After pneumonectomy and lobectomy the share of the residual and equilibrium capacities in the total capacity is clearly increased. This indicates a reduction of the respiratory efficiency. There occurs also an increase in the respiratory dead space, due probably to the increased lung inflation and to a certain extent, to emphysema.

Postoperatively dyspnea steadily diminishes and causes very little difficulty. If after lobectomy and pneumonectomy emphysema develops in the course of years, it appears to remain within moderate limits and not to encroach upon the lung function to any important degree.

SAMUEL KARRY, M.D.

Empyema Thoracis in Infants and Children. ALFRED E. CHAPLIN. *Arch. Dis. Childh.*, Lond., 1947 22 9.

A study of empyema thoracis in infants and children, covering two 5 year periods (1934-1938 and 1940-1944) was undertaken with a view of comparing the effect of sulfonamide therapy upon the incidence of the disease. A third group of cases consisting of 31 infants treated with penicillin since 1945 is discussed to illustrate the progress which has been made in the management of the disease in a most susceptible age group—the first 2 years of life.

During the period from 1934 to 1945 the author observed a reduction in the incidence of pneumococcal and streptococcal empyema in children and infants, and a reduced incidence of staphylococcal empyema in children of 2 to 14 years. Little or no reduction was observed in the number of cases of empyema or in the mortality figures for children from 0 to 2 years of age. Staphylococcal infections were observed as frequently as pneumococcal infections, if not slightly more frequently in the group from 0 to 2 years of age. The average mortality rate for all bacterial types of infection was 64 per cent for children 0 to 2 years of age.

It was concluded that penicillin plays an important part in the treatment of acute empyemas due to sensitive organisms. Penicillin may be injected parenterally and intrapleurally with aspiration of the pleural pus. Instillation of an adequate dose of penicillin every 2 to 3 days may produce complete resolution of the empyema in infants up to 2 years of age. From 2 years onwards, however, success with treatment by this method is unlikely unless the empyema is small. Aspirations are controlled by frequent radiographic examinations. Should the patient be slow to respond, and in the event of development of a thickened pleura surgical drainage is indicated. Similar interference is indicated in cases in which fibrin in the pus prevents adequate removal by aspiration. The intrapleural injection of penicillin should produce sterility of the pleural sac after one or two aspirations.

Rapid recovery with shortened convalescence occurred in both groups of infants—i.e. with and without surgical drainage.

STEPHEN A. ZIEGLER, M.D.

Discussion on Treatment of Nontuberculous Empyema. R. C. BROCK, and T. HOLMES SELLERS. *Proc. R. Soc. M. Lond.* 1947 40 645.

This article is a continuous discussion of nontuberculous empyema by two authorities. Brock considers an empyema as a localized collection of pus in the pleura, and a mature abscess as the end result of an acute suppurative process. The fundamental treatment of the empyema is reduced to 4 points: (a) assessment of the correct time for drainage, (b) provision of adequate drainage, (c) institution of proper physical treatment, and (d) decision as to the correct time to stop drainage.

Perhaps the most important thing we have learned in chest surgery from the war is that great success

can follow early evacuation of the clot and decortication of the lung in an infected hemothorax. A patient gravely ill with a chest full of infected clot which is breaking down, and often with a heavy mixed and foul anaerobic infection either dies or drifts into chronicity if treated by aspiration or by drainage alone. If treated by open thoracotomy and decortication of the lung and if the expansion of the lung is maintained by continuous pleural suction these patients get well can be completely healed in 2 or 3 weeks, and are left with a virtually normal chest. The operation is a severe one but is well tolerated if performed with simultaneous blood transfusion.

Scollors brings out the fact that chemotherapy can achieve good results. It is realized that chemotherapy, particularly penicillin therapy can achieve good results in diffuse and early infection, but its use in a local pleural abscess is open to definite limitation. Penicillin can certainly sterilize many of these abscesses but it cannot obliterate the actual cavity and persistence of the cavity beyond a certain stage increases the liability to formation of a chronic thick walled dead space. Scollors then discusses the method of closure of the empyema cavity after drainage, maintaining that 2 factors will prevent chronic empyema: (1) the maintenance of adequate drainage until the cavity is obliterated and (2) breathing exercises and physical treatment to restore respiratory function and to encourage the lung to re-expand.

STEPHEN A. ZIEGLER, M.D.

HEART AND PERICARDIUM

Studies of Cardiac Disturbances in Cases of Healed Traumatic Chronic Empyema of the Pleura
JAAKKO S. AALTO. *Ann. chir. gyn. fenn.* 1947 36 Supp. 2

The aim of this investigation was to clarify the importance of the cardiac disturbances in the degree of disability following chronic empyema cavities caused by war injuries. An endeavor has been made to find an answer to the following questions:

Is there a disturbed heart function and what is its extent in cases of healed traumatic chronic empyema?

To what degree is the disturbed function of the heart caused by intracardiac, and by extracardiac factors?

Which intracardiac and extracardiac factors are the most important in this respect?

Are the disturbances in the function of the heart severe or slight, and what is their prognostic significance?

In what way is the incidence of these disturbances affected by the duration of the primary disease and by the size and location of the empyema cavity?

The material comprises 58 cases, all males aged 20 to 49 years. Prior to being wounded, none of them showed symptoms of heart disease. As a result of war wounds 19 patients had a total chronic empyema 37 patients had a small or moderate sized

cavity limited to the lower or lower and middle part of the pleura and 2 patients had a small or moderate sized cavity in the upper part of the pleura. The cavity was on the left side in 31 patients and on the right in 27. All patients were treated surgically, the most frequent intervention being an extrapleural or intrapleural thoracoplasty often combined or supplemented by myoplastic operations of varying type and once by decortication of the visceral pleura. The primary disease and its treatment have left more or less extensive deformities in the chest: scoliosis of the vertebral column, pleural adhesions, rigidity and abnormal positions of the diaphragm, displacement of the mediastinum and its organs, pulmonary hernias and paralysis of the upper abdominal muscles.

The follow-up examinations in the different cases took place after periods of 1 month to 4 years had elapsed from the time of healing of the chronic empyema cavity. Two patients were examined 3 times, 25 were examined twice and 31 once. The follow-up examinations of the same patients were generally 6 months apart. Taking all examinations in the different cases into account the number of follow-ups was 41 in the first year after healing, 21 in the second, 15 in the third and 10 in the fourth year.

Besides an ordinary clinical examination the subjects were submitted to the following special tests: the pulse rate, arterial pressure, vital capacity, venous pressure and circulation time were observed during rest and after exercise. Special attention was paid to the electrocardiographic alterations during rest and at given intervals after exercise.

Although after the healing of the primary disease the majority of the patients showed subjective symptoms pointing to cardiac disorders, disturbed function of the heart could not be ascertained in any of the patients by means of ordinary clinical examinations. The pulse rate, arterial pressure, vital capacity, venous pressure, and circulation time determined during rest and after exercise corresponded with that of healthy individuals in at least four fifths of the cases. At the later follow-up examinations a decrease in the number of abnormal results was generally observed. As these results may be directly influenced by many extracardiac factors (and this was true in the present series) greater significance must be attached to the normal findings than to those diverging from the normal when evaluating the function of the heart. In all of the cases several of the 5 functional tests and in more than one third of the cases all 5 tests suggested a normal cardiac function. Definite conclusions cannot thus be drawn as to the presence of disturbed heart function on the basis of these tests. In view of the fact that results may be directly influenced by extracardiac factors, the results should be considered indicative of the general ability of the organism which is conditioned by several factors—in the first place by the state of the nervous system, the respiratory tract and the circulatory system. At successive examinations the

results in the cases studied showed the direction of development of the regenerative phenomena in the pathomorphological and physiopathological changes.

Electrocardiographic abnormalities are not generally caused directly by extracardiac factors, but arise as a result of disturbed cardiac function. For that reason the chief conclusions in the present investigation must be based on changes in the electrocardiogram. In addition the electrocardiogram particularly after exercise often indicates the cause of the functional disorder it does not however reveal the degree of the disturbance as a rule. Ordinary clinical examinations may to some extent support the electrocardiographic studies regarding the causes and degree of the functional disturbances. On the basis of the pulse rate arterial pressure vital capacity venous pressure and circulation time, conclusions may however be drawn only regarding the degree of the disorder.

In 24 of 58 cases electrocardiographic abnormalities indicated the presence of a disturbed function of the heart. In 14 cases the alterations were attributed to intracardiac factors. In 7 cases it was impossible to establish whether the causes were intracardiac or extracardiac and in 3 cases the symptoms suggested extracardiac factors.

The studies justify the assumption that the intracardiac causes of disturbed function of the heart are chiefly infectious infectious-toxic or anoxic changes in the myocardium. The changes caused by the infection arise principally via the blood stream, although a direct infection via the pericardium is also possible. A deficient oxygen supply to the myocardium may be due to anoxemia, possibly caused by pathomorphological and physiopathological changes in the chest and its organs, or to a decrease in the cardiac output which particularly in a part of the myocardium which is overburdened or has undergone myocarditic changes may easily result in anoxic changes. An overload on the right heart due to possible hypertension in the ordinary pulmonary circulation is then chiefly to be considered, as nothing has been noted at the examinations to indicate valvular disease. On the other hand a myocardium with deficient oxygen supply or an overburdened myocardium may be exceptionally susceptible to infective processes. It seems that in the cases in which the disturbed function has been attributed to intracardiac causes, myocarditic lesions, either alone or in association with anoxic myocardial injuries, are perhaps the most frequent. Extracardiac causes of functional heart disorders are especially those factors which cause a deficient oxygen supply to the myocardium and have not been sufficiently strong or long-standing to cause myocardial lesions. An other factor to be considered in particular is the exceptionally great lability of the nervous system in the present series of cases.

Decompensation was not observed in any of the cases. Routine clinical examination did not even reveal distinct symptoms of compensated heart disease. The functional heart tests showed that the

functional disorders were slight the tests also indicated that certain extracardiac causes of disturbed heart function decrease in the course of time. However definite conclusions regarding the prognosis can be drawn only by studying the cases closely over a long period of time.

The duration of the primary disease does not appear to influence the frequency of disturbed cardiac function. It is decidedly higher in cases in which the chronic empyema cavity has been larger than in cases in which the cavity has been small. The incidence of disturbed cardiac function is similarly higher if the cavity has been on the left side rather than on the right.

JOHN J. MALONEY M.D.

ESOPHAGUS AND MEDIASTINUM

The Sclerosing Therapy of Esophageal Varices.
Cecil O. LATTINSON and MILWARD O. ROCH.
Gastroenterology 1947 9: 39

Over a 4 year period 24 patients (26 were seen but 2 refused sclerosing therapy) have been treated for recurrent massive hematemesis by the injection of a sclerosing solution in the esophageal varices at esophagoscopy. The subjects ranged in age from 3 to 66 years.

These 24 patients had a total of 76 esophagoscopies with 209 injected sites receiving a total of 600 c.c. of 5 per cent sodium morrhuate. The average total injection per patient was 25 c.c. approximately 5 c.c. per varix punctured the minimum was $\frac{1}{2}$ c.c. and the maximum 24 c.c.

The incidence of episodes of hemorrhage would appear to have been significantly reduced as a result of the therapy based on a pre-injection incidence of bleeding. Of the 24 patients treated, 9 have died. Of the 9 who died 6 had hematemesis as a part of the terminal picture. The other 3 died of other causes without recurrence of hemorrhage.

Of the 16 patients under 40 years of age who had had splenectomy and were given sclerosing therapy 2 died. Of 8 patients under 25 years of age who survived splenectomy and had sclerosing therapy none died.

Fifteen of the patients treated were considered to have a cirrhotic liver 9 were believed to present Banti's syndrome and 8 of these had had splenectomy. The ninth patient has been advised to submit to splenectomy. Such corrective surgical treatment is considered necessary to the best results from sclerosing therapy. HIRSH T. LANGSTON M.D.

Gastroesophageal Resection and Total Gastrectomy in the Treatment of Bleeding Varicose Veins in Banti's Syndrome. DALLAS B. PIERCE and ELEANOR M. HUMPHREYS. *J. Am. Surg.* 1947 26: 397

Splenectomy portacaval shunt and injection of esophageal varices with sclerosing solutions have been the most reliable methods of controlling esophagogastric bleeding in Banti's syndrome. Splenectomy may fail to control the situation ultimately as

portal hypertension recurs. Portacaval shunt is not possible in certain situations and even when performed the stoma may narrow or close. The injection of sclerosing solutions has not been uniformly successful. Resection of the bleeding segment is another approach to management which even though it may throw an additional load on the remaining collateral routes may be justified because these segments either do not bleed at all or they bleed infrequently.

The detailed reports of 2 cases in which this approach in management was utilized are given. The first case had frequent severe hemorrhages from gastric varices after splenectomy and extensive obliteration of esophageal varices by injections. The liver was considered normal. Total gastrectomy was performed 3½ years ago. Only two attacks of hemorrhage have been experienced since one moderate and one slight in extent.

The second patient is free from bleeding 3½ months following a transthoracic esophagogastric resection performed for severe hemorrhage which had continued after splenectomy.

The study of the surgical specimen emphasizes the importance of gastric varices as a source of bleeding in addition to those present in the esophagus. The reports of these 2 cases are documented by numerous photomicrographs.

HIRSH T. LINGSTON, M.D.

Carcinoma of Esophagus. RICHARD H. SWIFT, J.
Am. J. Am. Surg. 1947 135:485

The author appraises the immediate and late results of resection and primary esophagogastric anastomosis for carcinoma of the esophagus or cardiac end of the stomach at the Massachusetts General Hospital, Boston, since it was first performed in 1939. There were 213 cases in the series and 66.2 per cent of the lesions were considered resectable. These figures include the resectability rate for carcinoma of the midthoracic esophagus as well as of the cardia and lower esophagus. There were 72 patients with midthoracic lesions, 50 of whom were operated upon and 741 patients with lesions of the cardia and lower esophagus, 91 of whom were subjected to resection. Seventy-nine of these latter patients survived the operation, 30 living for periods of from 6 months to 7 years, whereas of the 50 patients with midthoracic lesions who were operated upon, 30 lived for periods of from 6 months to 3 years.

The principal complications encountered after resection were infection, mediastinitis, cardiac, pulmonary and vascular disorders, and these rated high in the causes of death.

Dysphagia is the most distressing symptom of the disease and operation is considered the most effective single procedure in alleviating this pathetic disturbance. This is the opinion of the author and the fact that recurrence at the anastomotic stoma seldom develops thus giving the patient comfort for from 6 months to 2 years, make the operation worthwhile.

STEPHEN A. ZIEGLER, M.D.

Further Observations on Post Tracheotomy Mediastinal Emphysema, and Pneumothorax. GILBERT H. FOSSER, GEORGE SALVOY and JOHN C. HILBERG. *J. Pediatr. St. Louis*, 1947 31:173

The authors report their observations following tracheotomy in 120 children. Sixty-eight per cent of the children were under 2 years of age, 22 per cent were from 2 to 5 years old and 10 per cent were from 5 to 10 years old. They were carefully studied for signs and symptoms of mediastinal emphysema and pneumothorax. Seventy-four of the children were examined roentgenographically.

Twenty-five per cent of all children developed mediastinal emphysema and 10 per cent developed pneumothorax. Since the incidence of these conditions was higher among the patients who were examined roentgenographically it is believed that some cases among the remainder of the patients may have been missed.

The authors compare the incidence of mediastinal emphysema and pneumothorax among patients in whom the bronchoscope (or other airway) was in place at the time of operation with that among patients in whom the bronchoscope was not used. The development of mediastinal emphysema and pneumothorax was greater among the patients in whom the bronchoscope had not been used and indicates the importance of a free airway at the time of tracheotomy to prevent the suction of air into extrathoracic tissues.

Treatment consisted of the prevention of further infiltration of air. In the more serious cases, the air was sucked out with a needle and an oil syringe.

MISCELLANEOUS

An Evaluation of Methods of Penicillin Therapy in Thoracic Surgery. JOHN H. DONNELLY, FRANCIS J. PHILLIPS, J. P. BARTLETT and W. E. ADAMS. *Ann. Surg.* 1947 126:579

Believing that the penicillin titers in body fluids formed a more accurate appraisal of therapeutic effectiveness than mere clinical estimate of improvement the authors undertook the present study with particular reference to thoracic surgery. Penicillin levels in blood serum or pleural fluid after administration of the drug therefore form the basis of such appraisal. The routes of administration investigated were intramuscular, intratracheal, by inhalation of a combination with aerosol, and intrapleural.

The observations were made in human subjects in 85 instances and by 46 experiments on dogs. The observations in human beings and animals were generally well correlated except when the drug was given intrapleurally in which instance it seemed to be absorbed much more rapidly in dogs than in man. Also the inhalation method presented obvious mechanical difficulties in dogs.

The blood serum levels obtained following the administration of penicillin by the various routes is summarized graphically in the accompanying illus-

Penicillin Serum Levels Various routes

Fig. (Doanally *et al.*) Chart showing penicillin serum levels (units per c.c.) in the time shown following administration by various routes. (Courtesy of J. D. Lilly and Co.)

tration. More detailed data including maximal minimal and average levels for each of the investigations are presented however.

Concerning the levels in pleural fluid, it is seen that by the intramuscular injection of 40,000 unit every 3 hours good therapeutic level can be maintained 30,000 unit however are less effective. With intrapleural administration the pleural fluid level is high initially but it remains at effective levels for 4 or 5 days when 200,000 unit are used.

Intratracheal instillation and aerosol administration will produce short periods of effective blood serum levels, but their practical usefulness seems limited to local therapy for bronchopulmonary infections.

The intramuscular route is the best for providing desirable blood serum titers and will, when administered in 40,000 unit doses, produce therapeutically effective levels in pleural fluids.

H. W. T. LAWSON, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

The Subcutaneous Inguinal Ring: A Clinical Study
JAMISON L. CHERRIN *Surgery* 1947 23 540.

Of 5,956 subcutaneous inguinal rings in a 978 men studied by the author 78 per cent were large enough to admit the index finger without force. This is at variance with the published statements by a number of investigators. Of the 724 men whose subcutaneous rings were not bilaterally equal in size 57.5 per cent were larger on the left side whereas it is generally known that hernias occur more often on the right side. The author believes that there is no convincing proof that a large subcutaneous ring either is in itself abnormal or that it predisposes to the future development of hernias. He believes that it should not disqualify men from industrial employment.

ROBERT TURELL, M.D.

Internal Supravescal Hernia ROY MILLER, *Brit J Surg* 1947 35 84.

The author described a rare type of hernia known as internal supravescal hernia. The supravescal fossa is a triangular area bounded laterally by the obliterated umbilical vessels and below by the reflection of the peritoneum on to the dome of the bladder of peritoneum over the urachus. Below the peritoneal reflection is the potential space between the symphysis pubis and the bladder which is known as the prevesical space or the space of Retzius.

Men are affected more commonly than women in the proportion of 9 to 1. The small bowel is almost always involved, which causes symptoms of high intestinal obstruction. Most cases have usually been discovered at exploratory laparotomy. The treatment is that accorded to intestinal obstruction with strangulation. The hernia is reduced and the sac is obliterated. No recurrence has ever been reported following simple closure of the neck of the sac with interrupted or continuous sutures. In 37 authentic cases there has been a mortality rate of 40.5 per cent. When resection of the bowel is necessary the mortality is increased. In the author's case recovery followed reduction of the hernia and closure of the neck of the sac.

ROBERT TURELL, M.D.

GASTROINTESTINAL TRACT

Hematemesis and Melena. F AVERY JONES *Brit M J*, 1947 3 477

The change in the form of therapy in cases of hematemesis from a very restricted fluid intake and small transfusions to early feeding and frequent transfusions has been accompanied by a significant and marked drop in mortality. Liberal drip transfusions and early feeding actually reduce the risk of

Fig. 1 (Miller) Drawing showing the position of the hernia.

further bleeding and lower the mortality of recurrent hemorrhage. These statements are supported by statistical data. Autopsy reports of fatal cases treated by the older method show that in 18 of 39 cases the hemorrhage had ceased at the time of death and that many of the patients had not bled for some days previously. The authors believe that these deaths were due to uremia which was the result of the extreme dehydration brought on by the form of therapy.

Errors in diagnosis may arise disorientation from cerebral anoxia may be the presenting symptom and the melena may not be discovered until the patient is in the hospital. Dyspnea, edema and distended jugular veins may lead to an erroneous diagnosis of congestive failure. Cardiac pain from recent acute history of red blood in the stools may lead to the admission of the patient for hemorrhoids. Dark red fluid stools have often been observed after a brisk 'tarry' character may be misleading. Observations following the oral administration of citrated blood in man have shown that from 100 to 150 ml. of blood are necessary to produce a tarry stool while the administration of 2,000 ml. of blood by means of a Rehfuess tube into the upper gastrointestinal tract in a 4 hour period frequently resulted in stools extremely bloody but never tarry presumably from intestinal hypermotility. The appearance of the patient soon after the hemorrhage is extraordinarily misleading. The profound circulatory collapse and great clinical improvement. The initial pallor is probably due to the intense vasoconstriction which may occur as a response to hemorrhage. Fever after gastroduodenal hemorrhage is common and may persist for some days. The fever is not due to the presence of blood in the intestine but is possibly

related to the endogenous breakdown of body protein. The persistence of pain after a hemorrhage is well known to be uncommon, but the mechanism of this relief is unknown. Pain persisting after a hemorrhage is a bad prognostic sign and severe persistent pain has been noted only in fatal cases. Coronary thrombosis may be precipitated by the hemorrhage. Anemia is a well recognized and tragic complication of gastroduodenal hemorrhage; the vasoconstriction following bleeding may so severely reduce the blood supply to the optic nerve that irreversible damage from anoxia ensues.

It is well recognized that many of the patients with hematemesis and melena fail to show any evidence of peptic ulcer when a barium meal is given during convalescence. To investigate the cause of the bleeding in this group early gastroscopy was performed usually between the third and tenth day. In 60 per cent of these cases superficial acute ulcers were found to be the source of the bleeding, and because of their size and rapid healing they would not be visualized by barium meal later in the convalescence. Atrophic and hypertrophic gastritis is more rarely the cause of the hemorrhage. Patients bleeding from an acute ulcer had a much better prognosis than those bleeding from a chronic ulcer. Because of the much better prognosis of acute ulcers it is necessary to distinguish them if possible at the bedside, especially when the question of surgical intervention arises. Bleeding may be very severe from such ulcers and recurrence of the bleeding after admission is not uncommon. The pain of acute ulcers if present is never severe and has seldom lasted more than a week, while the absence of pain in these cases is a common history.

While heavy sedation should be avoided in the treatment, early reassurance and lessening of anxiety is important. A decision should be made early as to whether operation is to be considered if the patient bleeds again. An hourly pulse and blood pressure chart is kept and blood typing performed. The patient is allowed a semisolid porridge diet with 2 hourly feedings or 300 ml. of milk if preferred. Antacids are not essential but may be given. In severely ill patients with a long history a continuous milk drip may be of value at least during the night. If the vomiting reflex is diminished and the stomach distended with blood aspiration of the stomach is indicated. Oxygen therapy and the administration of vitamins B and C may be helpful. There was an 8 per cent mortality in the current series.

F J LEBERMAN, JR., M.D.

The Effect of Vagotomy on Human Gastric Function. ARTHUR M. SCHORN and R. ARNOLD GREEN. *Ann Surg* 1947 130: 655.

The authors summarize current opinion as to the etiology of ulcer and suggest that it may be secondary to (1) alterations of psychogenic or neurogenic origin, (2) alterations of the function of cells of internal or external secretion, (3) local alterations of the mucosal anatomy or physiology of the af-

fected mucosa, or (4) a reduction of the constituents of gastric contents produced by other organs such as the liver, pancreas, salivary glands, and the duodenum. It is likewise believed that the mechanism for the production and maintenance of peptic ulcer is the proteolytic activity of the gastric contents versus the mucosal resistance to devitalization and ulceration.

The purpose of this article is to point out a few of the common fallacies known to be present in the method used in determining gastric secretion by continuous gastric suction, and to describe briefly a new and more satisfactory method of measuring the function of the human stomach.

The method employed in this study of 30 patients consists of injecting into the empty stomach an isotonic solution containing a known amount and concentration of indicator (phenol red) and, after a 15 minute rest period, aspirating the entire gastric residual contents. From the values of quantity and concentration of indicator injected and aspirated, can be calculated the average rates of gastric secretion and emptying during the test period.

By means of this test it is shown that the gastric secretory response to histamine, a humoral secretagogue, is not prevented by complete vagotomy. Therefore a vagotomized stomach is still capable of producing active digestive juice. Complete vagotomy reduces gastric secretion and emptying by abolishing the cephalic phase of gastric function. Peptic activity, however, is least reduced.

In 6 patients, the basal gastric secretory rate was reduced by an average of 36 per cent following vagus resection. The authors conclude that the insulin test (hypoglycemia acts as a potent medullary stimulus to vagus function) for complete vagus nerve section appears to be satisfactory when carefully employed.

EDWARD F. LEWISON, M.D.

Gastric Neurectomy for Gastric and Duodenal Ulceration. WALTER WALTERS, HAROLD A. NELSON, WILLIAM F. BRADLEY, JOHN T. SALL, and JAMES W. WILSON. *Ann Surg* 1947 126: 1.

A study of the anatomy of the gastric nerves has demonstrated that in 92 per cent of the cases the nerves pass through the diaphragm as two distinct trunks and are readily accessible for resection.

The abdominal approach to the gastric nerves allows exploration of the abdominal contents, and especially the ulcer, if it is a gastric ulcer and is suspected of being malignant, it is removed and if the duodenal ulcer is obstructive or likely to become obstructive from gastric atony a drainage operation of the stomach is performed.

In the authors' series of 33 cases, it is important to remember that the disturbances of gastrointestinal motility were for the most part, temporary, although spasm of the pylorus with dilatation of the stomach and hypermotility of the intestine has persisted for several weeks in one patient operated upon for gastric ulcer. In one case gastric ulceration definitely recurred.

In the entire series of 66 cases, perforation of a duodenal ulcer and a subdiaphragmatic abscess caused the death of the patient 14 days after gastric resection and gastroenterostomy and 2 other deaths occurred 1 from a suspected cerebral embolism on the fourth postoperative day and the other at home from a heart lesion. This patient had been subjected to closure of a gastrojejunocolic fistula and gastric resection 3 months previously. In other cases the immediate results, as evidenced by reduction in gastric acidity, gastric secretion, relief of gastropasm and relief of pain were good but not striking. If the good results persist the operation offers an easy and a comparatively safe method of treating certain peptic ulcers, especially recurrent ulcers. It will have a limited application in cases of obstructing duodenal ulcer and in certain cases of gastric ulcer. In the former it can be used in a few cases in association with gastroenterostomy. In cases of gastric ulcer, excision of the ulcer should be done to exclude malignancy. When excision of the ulcer and gastric resection have been done simultaneously disturbances in gastric motility with retention and higher secretion have been troublesome. In any case however sufficient time must be allowed to pass to determine whether the good results are temporary as they seem to be in experimental animals and whether untoward results may develop.

Subtotal Gastrectomy for Gastric Ulcer HENRI K. RANSOM. *Ann. Surg.*, 1947 126 633

The author stresses the differences which exist between gastric ulcer and duodenal ulcer and summarizes briefly the characteristics of gastric ulcer. The present study represents the author's attempt to (1) ascertain the risk involved in operation for gastric ulcer and, to some degree, to determine the incidence of malignant growth; (2) make a critical analysis of clinical end results as far as the gastric ulcer problem is concerned and (3) discover the incidence and severity of certain side-effects of gastric resection such as postresection symptoms, nutritional disturbances and blood disorders.

The clinical material consisted of 1,356 patients treated for gastric ulcer during the 20 year period from 1925 to 1945 at the University Hospital, Ann Arbor, Michigan. Of this number 246 patients (18 per cent) required surgical intervention. End results of gastric resection for gastric ulcer support the view that this is the best means now at our disposal for the treatment of those ulcers which require surgery. The advent of vagal resection is mentioned primarily as an adjunct to gastric resection in an attempt to prevent jejunal ulcer.

The conventional subtotal gastric resection gave the best results regardless of whether a Polya or Hofmeister reconstruction was subsequently done. Three total gastrectomies were performed but the results were unsatisfactory.

In general the follow up end results were found to be satisfactory in 92 per cent of the cases and this compares favorably with any other major surgical

procedure. The operative mortality was 7.9 per cent, pneumonia and peritonitis being the leading causes of death.

The author stresses the fact that the proper therapy in gastric ulcer is still predicated upon one's ability to differentiate a benign from a malignant ulcer. In this series, microscopic study revealed malignancy in 10 per cent of gastric ulcers which even at the time of operation, were unrecognized as neoplastic. This error has been reported as even much higher at other clinics. Therefore as suggested by Graham and Lahey it seems just that patients who are suffering from what may seem to be a benign gastric ulcer be urged to accept partial gastrectomy early in the course of the disease. The operation in capable hands can be carried out without a prohibitive mortality and the number of carcinomas discovered will make the risk worth while.

EDWARD F. LEWISON, M.D.

Carcinoma of the Stomach DAVID STATT, GEORGE BLOOM, and OWEN H. WANGENSTEIN. *J. Am. Med. Ass.*, 1947 135 262

Gastric resection remains the only mode of treatment that is capable of curing gastric carcinoma.

Cancer ranks second only to cardiovascular disease as the commonest cause of death in this country. One-fourth to one-third of all deaths from carcinoma are due to gastric cancer. As the age of the population increases the number of persons who die from gastric carcinoma will also grow larger and it has been estimated that by 1960 as many as 40,000 patients will succumb to gastric carcinoma annually.

An exhaustive review of the world literature on the end results of the treatment of gastric carcinoma up to 1937 was compiled by Livingston and Pack. More recently Maimon and Palmer in addition to summarizing and analyzing their results at the University of Chicago brought the literature up to date. These authors called attention to wide variations in the published data from various institutions and emphasized the need of analyzing all published statistics with respect to four factors: the total number of patients with gastric cancer, the number of patients subjected to operation, the number of patients in which a gastric resection was done and the number of survivors in relation to the total.

The total number of patients with gastric carcinoma seen at the University of Minnesota Hospitals over a period of 10 years was 586. Of these 432 were men and 154 were women. The average age was 63.2 years. Nineteen patients were in terminal stages of the disease when first seen but their cases were included in the statistical data.

The number of patients operated on was 447, an operability rate of 76.3 per cent.

Three hundred and seven patients underwent gastric resection, a resectability rate of 52.2 per cent. In this group there were 31 total gastric resections and 276 partial resections.

The operative mortality among the 307 patients subjected to gastric resection was 16.6 per cent.

Among the 276 partial gastric resections, the operative mortality was 15.2 per cent and among 31 total gastric resections the operative mortality was 30 per cent.

Eighty five exploratory laparotomies were performed with a mortality rate of 8.5 per cent, 25 gastrojejunostomies with a mortality rate of 24 per cent, and 30 enterostomies with a mortality rate of 13.4 per cent.

There were 51 deaths following gastric resection and in 44 of these it was possible to obtain autopsies. The major cause of death was peritonitis which accounted for 28 fatalities. 8 patients succumbed to pulmonary complications. 4 died of cardiac failure, 3 of renal complications. 2 of pulmonary embolism, 1 patient died of cerebrovascular accident, and 1 of shock. In 4 cases the cause of death was undetermined.

Because sufficient time has not elapsed the percentage of patients surviving for periods of 3 and 5 years can only be determined in relation to those patients who were operated on in the periods from 1936 to 1943 and from 1936 to 1941. The percentage of patients surviving 5 years after gastrectomy was 10.7 per cent, but based on the number of patients subjected to gastric resection it was 20.4 per cent. The percentage of patients surviving 5 years was 6.6 per cent, but determined on the basis of the number of patients surviving gastric resection it was 21.5 per cent.

Gastric resection was the only palliative procedure of value. The average number of months of palliation following gastric resection was approximately 22. In the main the patients were comfortable up to the last few weeks before their death.

The operability and resectability during the 10 years of study have increased markedly. In 1936 the operability and resectability rates were 37 per cent and 28 per cent whereas in 1945 these rates were, respectively 88 and 80 per cent. The resectability rate for 1945 based on the number of patients explored was 80.7 per cent. The mortality rate for partial gastric resection in 1936 was 15 per cent, while in 1945 it was 4.9 per cent, which figure includes both total and subtotal gastrectomy.

HARRY W. FINE, M.D.

Report of Prolonged Follow Up Study of 2 Patients who Underwent Partial Gastrectomy When Young. PAUL MCGUFFY and CARL G. MORLOCK. *Gastroenterology* 947 9: 307

The need for a major surgical procedure of any type on the stomach of a child is infrequent. Rarely indeed is it found needful to sacrifice the greater portion of a child's stomach. Because of this and the attention that has been drawn to the nutritional disturbances which sometimes follow partial gastrectomy the authors deemed it worth while to report the cases of 2 patients who underwent partial gastrectomy when young and were followed up for a total of 21 and 30 years respectively. Normal physical development and excellent health have been the

experience of one patient. Half of this patient's stomach had been removed when she was 10 years old. In the second case, approximately a fourth of the stomach was removed. The patient was 16 years of age. Postoperatively she developed normally and remained well for 30 years, except for some difficulty in maintaining her weight.

Peptic Ulcer: A Diagnostic and Therapeutic Problem. SARA M. JORDAN. *Gastroenterology* 947 9: 317

Among the large group of diseases influenced by psychic factors there is probably none in which the psyche plays any greater part than in peptic ulcer. Therapeutic measures are deficient if they fail to include adequate protection of the mental and nervous state of the patient. In any consideration of physical conditions with psychosomatic aspects, however it must always be remembered that the somatic factor is a real one, and that there may even be a somatopsychic as well as a psychosomatic interplay.

Opinion is now rather general that peptic ulcer is associated in origin with a combination of three factors: increased muscular contraction which is commonly termed spasm, increased secretion of hydrochloric acid, and decreased resistance of the mucosa to these two abnormal factors. The basic etiology behind these factors remains unidentified. There is an etiologic influence from the mind and nervous system upon the genesis of ulcer. It is likewise certain that other influences also play an etiologic role—such as infections elsewhere in the body e.g. respiratory infections, the toxic effects of alcohol and smoking, habitual irritation from food which is difficult of digestion. And behind all these influences there must, of course, be a predisposing factor which causes certain individuals to be gastrically and intestinally sensitized to these influences, while others are entirely resistant. Whether that basic predisposition is dependent upon localized diminished resistance or upon a hormonal defect, or upon some other as yet unconceived factor remains an unsolved problem.

Once a diagnosis of peptic ulcer is accurately made it carries with it certain very definite therapeutic involvements some of which may be permanent throughout the life of the patient. It is of prime importance to the patient that a timely diagnosis be made so that a decision concerning later habit restrictions or lack of restrictions is logically made. Clinical experience tends to show that peptic ulcer is too infrequently diagnosed rather than too frequently diagnosed. The typical ulcer history is well defined, its main points being periodicity and time relationship to meals, coupled with relief by food, even cold food, and by alkalis. A history of ulcer may however become completely atypical when other disease organic or functional, such as a cholecystic lesion or an irritable colon, masks the clinical picture. In this respect one must always analyze carefully the history of a suspected ulcer recurrence, inasmuch as certain of the therapeutic measures for ulcer especially magnesium and the silicates, may

produce a small intestinal and colonic irritability the symptoms of which may be confused with those of recurrent ulcer. Extreme care in eliciting and evaluating the history is essential in these cases since important determinations for or against radical treatment are often made on the basis of relief or failure of relief of symptoms and symptoms cannot be effectively relieved unless adequately diagnosed.

The diagnosis of peptic ulcer is never aided by physical examination of the patient except when confirmatory evidence is supplied by the finding of localized tenderness. Chemical findings particularly free hydrochloric acid and occult blood in stools are significant diagnostic data. An active duodenal or jejunal ulcer is rarely seen without high acid findings, and the course of healing of duodenal ulcer may often be gauged by the change in acid values. It is unnecessary to use fractional analysis in most cases—an Ewald meal and aspiration 45 minutes later gives adequate data. In gastric ulcer only the presence or absence of free acid is important, since an active gastric ulcer is less commonly attended by hyperchlorhydria than is the duodenal lesion. In untreated cases achlorhydria should be regarded as a finding suggestive of malignancy however the corollary of this statement, namely that gastric carcinoma is always attended by achlorhydria, is not dependable since probably 40 per cent of patients with gastric carcinoma have free acid. The finding of occult blood in the stools is important only when conditions of food intake and gum bleeding are very carefully controlled. Under these circumstances of course persistent occult blood means unhealed ulceration and if this continues under treatment of a gastric ulcer malignancy must be suspected.

X-ray and endoscopy particularly when the latter supplements the former, are our best aids in the diagnosis of esophageal and gastric ulcer and x-ray alone in the diagnosis of duodenal and jejunal ulcers. In about 30 per cent of cases it is impossible to make an accurate diagnosis of peptic ulcer without the use of fluoroscopic as well as film examination. In all cases fluoroscopy supplements film examination to such an important degree that it should never be omitted. This is especially true when there is a question of supplanting medical with surgical treatment or when a patient with ulcer is under treatment and the course of healing or the question of recurrent activity is being determined. Irritability in the still active or recurrent duodenal or jejunal ulcer is indicated by rapid filling and emptying of the bulb or by marked spasm in the duodenal bulb or at the stomach. One of the most valuable procedures developed during the last 10 years of radiographic work with peptic ulcer is the visualization of the rugal pattern of stomach, duodenum, and jejunum. The grossly deforming ulcer of the duodenal bulb is obvious both in the fluoroscopic and film examination. However a differentiation must often be made between the active and quiescent ulcer and fluoroscopy is then the best diagnostic aid since it reveals rapid filling and emptying and spasm so characteristic of the ac-

tive phase of ulcer. One of the fundamentals of good gastroenterology is complete familiarity with fluoroscopy and film reading. The knowledge of the physiology and of the pathologic abnormalities and aberrations of the digestive tract obtained by skill in this field is a priceless acquisition for the gastroenterologist.

The therapeutic measures have in large measure been directed toward the neutralization of gastric acidity and the alleviation of spasm. The problem of gastric ulcer is a different matter. Here we are dealing with a lesion of which we know that it is some times a wolf in sheep's clothing—that it may look like a benign ulcer and yet harbor malignant changes within itself which sooner or later will convert it into an invading carcinoma. The question arises can gastroenterologists take the responsibility of differentiating between the lesion which is potentially innocent and that which is or will be malignant? If they use adequate caution they can. The unhealed ulcer and the recurrent ulcer when located on the gastric side of the pylorus are the threat to safety in other words it is the question of chronic irritation in a terrain highly susceptible to malignant changes. Two principles should be observed meticulously the first that the gastric ulcer however benign it may appear should be closely watched to the point of absolutely complete healing a process which should occur within 3 to 5 weeks at the most. The criteria for healing are the same as have been used in the past—that symptoms, occult blood, and x-ray defect shall completely disappear with trial management, but many cases are checked gastroscopically as well as by x-ray for complete healing. All recurrent gastric ulcers, however benign they may appear to be must have gastric resection. If these two principles are carefully observed gastric carcinoma in an ulcer will not be missed.

A survey of gastric ulcers is being carried out it is still incomplete but figures thus far indicate an incidence of about 10 per cent malignancy in lesions which looked like ulcer and of about 5 per cent in cases in which continued medical treatment was too long. The differentiation of duodenal ulcers as to whether they should be treated medically or surgically is chiefly a matter of tractability. The duodenal ulcer with complications is also often a surgical problem. Here, however two observations based on experience should be made (1) the obstructed ulcer is often not truly obstructed (2) the ulcer with a history of multiple hemorrhages may prove to be as unsatisfactory after surgical as after medical treatment. With regard to obstruction in many instances apparent obstruction is due not to cicatricial narrowing which requires surgical intervention, but to edema and inflammation from an acute ulcer which is relieved by a few days medical management and will not recur if the ulcer heals and remains healed. The adequacy of previous medical treatment should be given careful consideration before surgical intervention is advised. A few days of hospital rest under an ulcer management based on the Sippy regime though

often modified to the individual requirements, results in clinical relief of all symptoms and in x-ray evidence of healing, unless the ulcer is intractable. In cases in which night pain has been a feature, this is relieved in a few days by nocturnal hourly administration of a neutralizing medication, if it is to be controlled at all by medical management. Tractability is, therefore, easily determined clinically as well as by x-ray within a very reasonable time a week at the longest. This fact, in addition to the very compelling reason that rest, neutralization and education can best be accomplished with the patient in the hospital under constant observation makes hospitalization most advantageous.

Enterogastrone and vagus resection are fledglings whose development merits careful observation with the hope that either one may provide a short cut in ulcer therapy if an ulcer is detected early enough and often even when it is diagnosed late if it is treated intensively by the routine method of rest and neutralization good results can be expected and with thorough education of the patient as to the nature of the disease and with his co-operation or control, permanent freedom from recurrence may be expected.

CHARLES BARON, M.D.

Gastric Neurotomy: Anatomic and Physiologic Studies with Favorable and Unfavorable Results in the Treatment of Peptic Ulcer WALT MAM WALTER, HAROLD A. NEUBERG, WILLIAM F. BRADLEY, JOHN T. SMALL, and JAMES W. WILSON. *Arch. Surg.* 1947 55: 5

Reports of other surgeons led the authors to study the problem of resection of the vagus nerves, or as they prefer to call the operation, gastric neurotomy, from the anatomic, physiologic, and chemical standpoint in 40 patients operated on at the Mayo Clinic up to January 15, 1947.

Only brief reference will be made to additional cases in which operation was performed by other surgeons at the clinic, for they will individually report on their results in detail later.

Anatomic dissections of the gastric nerves made on 56 men, 44 women, and 11 children during the course of postmortem examinations indicated that the gastric nerves could be located and successfully resected near the diaphragm by either a transabdominal or a transthoracic approach in approximately 93 per cent of the cases, and that possibly most, if not all, of the branches in the remaining 8 per cent also could be located in the same way.

Results of gastric neurotomy are inconstant, variable and, in most cases, unpredictable. The relief of pain obtained may be the result of the release of gastroparesis and a reduction in gastric acidity as a result of the interruption of cephalic stimulation. The expense of this relief of pain is dilatation of the stomach with frequent troublesome retention of gastric secretion and, in some cases, food remnants. Moreover that relief of pain is not the result of healing of the ulcer must be considered since in one case acute perforation of duodenal ulcer developed.

In one case a gastric ulcer recurred in other cases failure of the ulcers to heal has been demonstrated pathologically at subsequent operations necessitated by a continuation of bleeding or a marked degree of gastric retention which interfered with the patient's nutritional state.

Reduction in gastric acidity although it has occurred in most cases, is inconstant in others and the disturbances of motility of the stomach and small intestine are frequent after operation. In some cases these disturbances are temporary and in others prolonged, persistent, and troublesome to the patient. In such cases patients have complained of frequent belching of foul smelling gas, fullness and bloating after meals and a few patients have complained of nausea and diarrhea. Subsequent operations have been necessary in some cases to remove the persistent ulcer or to provide drainage.

There have been three hospital deaths in these 83 cases. Although 3 of these could be directly attributed to cardiovascular accidents, 1 patient died of unsuspected perforated duodenal ulcer with a subdiaphragmatic abscess. Gastroenterostomy had been done at the time of the gastric neurotomy. Another patient died from a coronary occlusion at home, 3 months after the closure of a gastrojejunal colic fistula.

In evaluation of the results of the operation, it must be proved that an ulcer is present and that the gastric nerves have been completely sectioned. It is the opinion of the authors that the best approach in most cases in which gastric neurotomy is contemplated is by means of a transabdominal incision for this approach permits exploration of the gastro-intestinal tract and such procedures as are necessary to supplement the gastric neurotomy. The greatest field of usefulness for the operation seems to be in the treatment of ulcers after partial gastrectomy and in certain cases of nonobstructive duodenal ulcers in which the cephalic phase of gastric secretion is marked and pain is intractable.

In view of the inherent ability of the gastro-intestinal tracts of human beings, like that of animals, to regain through compensatory mechanisms their function after operative procedures which disturb the neuromuscular continuity and in view of the fact that restoration of gastric acidity and gastric motility has occurred within a year in dogs in which gastric neurotomy has been performed, the possibility of such a return in human beings must be kept in mind.

For the time being the operation of gastric neurotomy will have to be considered as in the investigative stage.

The Management of Patients with Massive Hemorrhage from Peptic Ulcer SERRAUX J. GAY. *Med. Clin. N. America*, 1947 3

Every patient admitted to the hospital with a massive hemorrhage from the upper gastrointestinal tract must be considered a potential fatality. The management of this condition is a challenge, and

sound clinical judgment and the constant observation and re-evaluation of the status of the patient are essential.

Definite establishment of a diagnosis is imperative when a patient is admitted with hematemesis or tarry stools associated with dizziness, weakness, tachycardia and perspiration.

Peptic ulcer causes 75 per cent of all massive hemorrhages. A history of previous ulcer or ulcer distress, previous attacks of hematemesis or melena, or positive x ray evidence of a crater or deformity indicates ulcer as the possible source.

Hypertrophic or erosive hemorrhagic gastritis, esophageal varices, cancer of the stomach, gastric polyps, diaphragmatic hernia, or blood dyscrasias are other sources of hemorrhage.

When the diagnosis is still uncertain after the workup is complete, roentgen examination may be undertaken from 24 to 48 hours after severe hemorrhage or earlier provided the patient is not in shock.

The state of shock, hemorrhage and dehydration must be evaluated and treated. The blood type, including the Rh factor and cross matching should be determined first. Repeated hemoglobin, red blood count, and hematocrit determinations are necessary. A low blood prothrombin time is not infrequently seen in patients with massive hemorrhage from an ulcer. Vitamin K is helpful in these cases. All stools and vomitus should be examined for gross and occult blood as an aid in evaluating the extent and course of the hemorrhage. Plasma proteins, blood urea nitrogen, blood chloride, and carbon dioxide content of the blood must be followed up carefully.

Massive transfusions if given slowly do not cause an appreciable rise in blood pressure and do not produce further hemorrhage. Blood transfusions combat shock, exsanguination and hypoproteinemia and tend to exert a beneficial effect upon the patient's welfare. The contraindication of post-transfusion reaction has been eliminated almost entirely by typing, cross matching and determining the Rh factor in each case.

During the first 48 to 72 hours, parenteral fluids are necessary to maintain the circulating blood volume, re-establish the normal electrolyte balance, and combat dehydration and azotemia. Enough fluids should be given (electrolyte requirements as indicated by the blood chemistry) to maintain an adequate daily renal output. Excessive amounts of fluids and too rapid administration should be avoided. The total daily intake should approximate from 2,000 to 2,500 c.c.

The starvation treatment of bleeding ulcers is outdated as the empty stomach neither prevents the secretion of acid nor decreases gastric motility. Small hourly feedings should be given if they are tolerated by the patient. This maintains the nutritional state, arrests hemorrhage by reducing the gastric acidity and decreasing the gastric motility and speeds blood regeneration. Patients treated this way have a lower mortality than those treated with the starvation regimen. Hourly feedings of 100 c.c.

of milk and cream should be given from 7 in the morning to 10 at night and feedings continued at 3 hour intervals through the night. This routine is continued till the stools are negative for occult blood for 3 days. The usual ulcer regimen with supplementary small feedings is gradually changed to a 3 meal management within 2 weeks. Intubation should be avoided in patients with massive hemorrhage.

High acid gastric juice may favor the extension of the ulcer and may digest the fibrin clot which forms at the bleeding point. As complete and constant neutralization of acid secretion throughout the day and night is desired, further neutralization than can be achieved with milk and cream may be necessary. Calcium carbonate, tribasic calcium phosphate, tribasic magnesium phosphate and aluminum hydroxide are recommended. The addition of from 5 to 10 c.c. of colloidal aluminum hydroxide to the hourly milk and cream is adequate antacid therapy.

Reassurance, good nursing care and sedatives contribute appreciably to the success of the treatment. The patients should be kept in bed until all evidence of bleeding has disappeared and the hematocrit and hemoglobin are within normal ranges.

Antispasmodics such as atropine, in a dose of 0.6 mgm. 4 times a day reduce motor and secretory activity of the stomach.

Secondary deficiencies of vitamins C and K may be avoided by the use of parenteral or oral supplements.

The treatment of choice in acute massive hemorrhage from peptic ulcer is medical but the possibility of a fatal hemorrhage particularly in patients over 50, should always be considered. Surgical intervention should be carried out when necessary within from 24 to 48 hours as the mortality increases rapidly after this period. The surgical service should see all these patients in order that delays may be avoided if surgical intervention becomes necessary. Subtotal gastrectomy is the treatment of choice as simple ligation of the bleeding points is unsatisfactory and leads to secondary hemorrhage. Each case must be judged individually. A hemorrhage is more likely to be fatal in a patient over 50. Fatal hemorrhages are less likely in women than in men. Chances of recovery are better after multiple hemorrhages than after the initial hemorrhage. Certain medical contraindications to emergency surgery may be present. Approximately 70 per cent of the patients with 2 or more hemorrhages are likely to suffer from further hemorrhage. If there are no contraindications, elective surgery should be contemplated for this group. Careful gastroscopic examination to determine the presence or absence of gastritis should be carried out prior to any surgery.

The management of older patients with massive hemorrhage from peptic ulcer presents a difficult problem. Short summaries of the cases of 6 patients between 65 and 70 years of age are given.

All patients who have experienced a massive hemorrhage from peptic ulcer should be observed and studied periodically after their recovery.

ROBERT R. BIGELOW, M.D.

Vagus Resection for Ulcer: An Interim Evaluation
FRANCIS D. MOORE. *Ann. Surg.* 1947 126 664

In a previous article the author describes the operative technique, postoperative management, and hospital morbidity and mortality of vagus resection for ulcer at the Massachusetts General Hospital, in Boston. In his present contribution he reports the clinical results obtained in these patients 2 to 30 months after operation.

It is pointed out by the author that vagus resection for ulcer is at the crossroads, that it is well known as an effective weapon in dealing with ulcer and that the approximate magnitude of the operative side-effects is also known as well as the degree of its failures. The accumulation of factual information must now be utilized to balance the significant advantages against the shortcomings so as to arrive at an evaluation of lasting significance.

The results following vagus resection for ulcer in 74 patients (both private and charity) at the Massachusetts General Hospital are analyzed and a satisfactory end result was reported in 90 per cent of the cases.

Among the side-effects following vagus resection diarrhea was present in 62 per cent of the cases, but it was minor or transient in all but a few cases. Emptying disorders were less common and less important than diarrhea and were taken as a matter of course in most cases. Severe wound pain was uncommon despite the fact that the patients in this series of cases were operated upon by the thoracic route.

Good results were obtained in patients who were intractable to all other forms of therapy, including subtotal gastrectomy. The author believes that vagus resection is an addition to the surgical armamentarium and that it may come to occupy a permanent and important place, although a reserved attitude must be maintained until the present groups of patients have been followed longer.

EDWARD F. LEWISON, M.D.

Resection and Primary Anastomosis in the Treatment of Gangrenous or Nonreducible Intussusceptions in Children CLARENCE DIERKS.
Ann. Surg. 1947 6 788.

During the period between November 1, 1940 and March 1, 1947 the authors performed 8 resections for intussusception at the University of Minnesota Hospital, Minneapolis. Exteriorization and delayed closure was done in 1 case and primary aseptic anastomosis in 7 cases. All patients recovered. The indications for resection were infarction of intussusception in 5 cases; recurrent intussusception with polypoid Peyer's patch in 1 case; developing recurrence while being observed for viability, and Meckel's diverticulum in 1 case; irreducible intussusception due to a large polyp in 1 case.

The choice of procedure lies between exteriorization and early closure on the one hand and resection and primary closure of anastomosis on the other. With a background of closed anastomoses, the latter

course is preferred here. A simple and safe type of one layer closed anastomosis with silk sutures was presented.

CHARLES BARNOW, M.D.

Duodenal Regurgitation. ARTHUR R. MITZ. *Arch. Surg.* 1947 55 239.

The author considers duodenal regurgitation as a clinical entity that has not received proper emphasis by clinicians in previous years.

Its most common cause is pressure on the duodenum by the mesenteric attachment where this part of the intestine passes over the spine. Obstruction may also result from lack of proper rotation of the intestinal tract, tumor or adhesions. It is usually associated with ptosis of the abdominal viscera.

Symptoms vary with the degree of obstruction. When slight there are recurring attacks of nausea, with disturbed appetite and weight loss. As the obstruction becomes more marked the attacks of nausea increase and are followed by a sense of fullness in the right upper area of the abdomen and by vomiting; these commence after the patient begins eating. In the progressive case the anorexia and pernicious vomiting result in extreme dehydration, emaciation, gradual exhaustion and death.

This condition should be suspected from a history of repeated nausea and vomiting not explained by ordinary causes. A positive diagnosis is made by fluoroscopic examination of the stomach and duodenum. The stomach is large and J-shaped with a highly placed outlet. The duodenum is dilated to several times its normal size. A barium meal will be observed to stop at the right of the spine, churn back and forth because of hyperperistalsis and then regurgitate back into the stomach. After a delay of several minutes the barium may be forced over the spine to move along its usual course.

Treatment depends on the severity of obstruction. When slight, medical management should be instituted: regulation of food intake, rest at mealtimes, and various positions of the body postprandially. Further treatment consists of bed rest and frequent small feedings. If the patient does not make satisfactory progress with this type of therapy surgical intervention is indicated.

The accepted surgical procedure is duodenojejunostomy which gives complete relief. Care must be taken to make a large stoma to permit prompt emptying of the distended duodenum. Another operation used is a posterior gastroenterostomy with pyloric occlusion.

The author mentions the cases of 15 patients, 10 relieved by gastroenterostomy and 5 by duodenojejunostomy.

C. FREDERICK KITTLE, M.D.

Some Physiologic Aspects of the Surgical Treatment of Duodenal Ulcer JAMES T. FAHRELEY.
Surg. Clin. N. America, 1947 27 905.

It is generally agreed that medical treatment should be instituted in all cases of duodenal ulcer except those in which certain complications are present. Experience at the Mayo Clinic indicates

that approximately 85 per cent of all patients with this condition can be treated medically. Complications which are considered to indicate the desirability of surgical treatment, and which will be discussed only briefly may be listed as primary or secondary obstruction, perforation, failure of hemorrhage ob-
 ment and any doubt as to the benignity of the lesion.

At present it is the practice at the clinic to institute medical treatment in all cases in which massive bleeding from duodenal ulcer occurs. If after medical treatment has been continued for 48 hours there is still evidence of continued or recurrent bleeding immediate surgical intervention is desirable.

For the patient who has had several episodes of bleeding one is always a little more inclined to suggest surgical treatment. This is especially true if bleeding occurs under ordinary circumstances when the patient has been taking at least fairly good care of himself. Medical treatment which failed to prevent hemorrhages in the past hardly can be considered adequate to prevent hemorrhage in the future.

Obstructive lesions caused by duodenal ulcer may be either inflammatory or sclerotic in nature. The inflammatory type of obstructive lesion usually is seen during a subacute exacerbation of symptoms. Under proper medical treatment, symptoms of obstruction generally disappear in a week or 10 days. It is doubtful however whether more than one or two such episodes should be treated medically because they are likely to recur and cause sclerotic narrowing of the duodenum. When a definite cicatricial type of obstructive lesion results there is little to offer but surgical treatment.

Perforation by a duodenal ulcer may be either a subacute or an acute process. All agree that acute perforation of a duodenal ulcer constitutes a surgical emergency. The subacute perforating duodenal ulcer generally is one of pronounced activity causing varying degrees of penetration through the wall of the duodenum. In the advanced case the entire thickness of the duodenal wall has been eroded and the base of the crater consists of adjacent tissue, usually pancreas. When an ulcer of such pronounced activity is present it is unlikely that medical management will result in satisfactory cure.

Failure of medical management to relieve symptoms of ulcer long has constituted an indication for surgical treatment. Care must be exercised however in determining just when failure of medical management has occurred. One should be confident that an adequate regimen has been followed.

Occasionally uncertainty will exist regarding the exact diagnosis in a case of duodenal ulcer. This occurs most often when the lesion is situated at the pylorus and the roentgenologist is unable to say whether it is actually in the duodenum or on the gastric side of the pylorus. A small carcinoma in this vicinity may closely simulate a duodenal ulcer. If any doubt exists as to the benignity of the lesion surgical exploration should be advised. Thus, if an obstructing lesion at the outlet of the stomach is

thought to be a duodenal ulcer but the gastric acidity is low and perhaps free hydrochloric acid is absent, exploration should be performed.

Besides these primary indications for surgical treatment of duodenal ulcer there are certain factors of secondary importance the presence of which tends to favor surgical intervention. These include a very unfavorable economic status, which virtually prevents the patient from making adequate trial of medical management, the unco-operative nature of a given patient whereby the dietary regimen is not followed, excessive gastric acidity with a value of free hydrochloric acid possibly of 80 or more (Töppfer's method), a history of duration for many years and symptoms of marked severity. While no one of these secondary factors alone should be considered to constitute a definite indication for operation, when two or more of them exist in the same case, thought should be given to the advisability of operation.

Although one hears many words of condemnation for gastroenterostomy many patients have experienced an eminently satisfactory result after this operation. It seems that this fact should be kept in mind because if this operation is performed with proper indication and its technical execution is correct, good results may still be expected in a large majority of cases. True the possibility of occurrence of jejunal ulcer always remains, but that possibility also exists to a less extent after gastric resection. It should be remembered that in the hands of the average surgeon, gastroenterostomy entails a definitely lower operative risk than does gastric resection.

Gastroenterostomy may be performed as an operation of choice or at times as one of expediency. The patient who qualifies in the former category would be as a rule, of advanced years would constitute a poor surgical risk would have a chronic lesion of long standing perhaps causing obstruction because of sclerotic changes would have relatively low gastric acidity would present a single lesion and no appreciable associated gastritis and would exhibit a minimal neurogenic factor. At times gastrojejunostomy may be employed in the absence of many of the conditions just mentioned if the technical aspects of gastric resection involve too great difficulty or hazard. Such may be the case in dealing with an ulcer deeply placed in a shortened duodenum which permits neither removal of the ulcer and satisfactory closure of the duodenal stump without jeopardizing the common bile duct nor section of the duodenum immediately distal to the pylorus and satisfactory closure of the duodenal stump. This type of lesion in an obese individual with a high lying stomach and deeply placed duodenum makes resection more difficult and hazardous and therefore, may make advisable something less desirable than the surgical procedure of theoretic choice. As the surgeon's experience increases technical considerations of this type become less of a factor in his choice of operative procedure.

While there is more than one way of making a gastrojejunostoma that will permit satisfactory

gastric motor function the preferred type is as follows. The stoma is placed on the posterior wall of the stomach and is extended almost from the lesser curvature down to the greater curvature in a line running approximately from the patient's right shoulder to his left foot with the proximal jejunal loop fixed to the lesser curvature of the stomach and the distal loop joined to the greater curvature. The point at which the distal jejunal loop is attached to the greater curvature of the stomach should be directly below the angle of the lesser curvature. One should remember that an enlarged obstructed stomach will decrease in size after relief of the obstruction with a corresponding decrease in size of the gastroenteric stoma. Two or three rows of sutures may be used. Fine suture material is preferred. The stoma in the jejunum should be placed directly opposite the mesenteric border. Less than 5 cm. of stomach or jejunum should be inverted into the gastroenteric lumen particularly at the point at which the distal loop of jejunum leaves the stomach.

The retrocolic type of anastomosis is preferred. The transverse mesocolon should be sutured to the gastric wall at least 2 cm. removed from the site of anastomosis around the entire stoma. The surgeon must be certain that these sutures actually are placed in the gastric wall in the region of the greater curvature and not in the gastroduodenal omentum. This requires that several sutures be passed through the gastroduodenal omentum and into the anterior gastric wall at the lower angle of the anastomosis. A short proximal jejunal loop should be used, one just short enough, perhaps 8 to 10 cm. in length to permit approximation of the jejunum to the lesser curvature of the stomach without tension yet without appreciable redundancy. At the conclusion of the operation the distal loop of jejunum should be placed so that it lies to the patient's left in the region of the root of its mesentery.

Until vagotomy has had time to prove itself gastric resection probably should be used in approximately 5 out of 6 cases of duodenal ulcer. Resection is not an ideal procedure for treatment of duodenal ulcer and it is possible that as time passes this procedure may be supplanted gradually by one or more forms of medical or surgical treatment. At present the ideal patient for gastric resection would be a man of middle age in good general condition who has failed to obtain relief despite careful and prolonged adherence to a medical regimen whose gastric acidity is high, who perhaps has experienced recurrent hemorrhages and who has an active lesion for which resection would not be unduly difficult or hazardous. The presence of multiple ulcers and associated gastritis, as well as of a large neurogenic element would favor resection rather than conservative operation, however none of these factors makes for a favorable postoperative result.

The Billroth I type of anastomosis is preferred to the Billroth II. More specifically preference is for the Schoemaker modification of the Billroth I type, in which resection of the stomach is carried higher

along the lesser curvature than the greater curvature and the end of the stomach after closure of the lesser curvature to the desired point, is anastomosed directly with the end of the duodenum. To accomplish this operation one must have an adequate amount of duodenum distal to the ulcer that can be mobilized with a good blood supply. Anastomosis must be accomplished without tension and without limitation of resection of the desired amount of stomach. The end of the gastric stump is so formed, by appropriate closure of the lesser curvature, that its size corresponds with that of the duodenum. The amount of stomach and duodenum incised into the gastroduodenal stoma should be small in order that an adequate gastric outlet may be maintained. Although crushing clamps may be used, the author's preference is for the so-called open anastomosis performed by the use of rubber-covered Doyen forceps.

In a Billroth II type of resection it has been well demonstrated that short-loop retrocolic anastomosis is followed by results superior to those obtained when long-loop antecolic anastomosis is employed. This latter type which is technically easier to perform, at times may be used for expediency if the patient is fat, the transverse colon short and thick, and the stomach is small and in a high position. Entericanastomosis between the jejunal loops is unnecessary and undesirable. One may anastomose the entire end of the stomach with the jejunum, or only a part of it after closure of the portion bordering the lesser curvature according to the method of Hofmeister; the latter procedure is the favored one. None of the prepyloric portion of the stomach should be permitted to remain. Removal of the duodenal ulcer itself is unnecessary so long as satisfactory closure of the duodenal stump is obtained. In practice the ulcer is removed almost invariably. Satisfactory closure of the duodenal stump is most important; likewise it is essential that there be no aspliation or other factor which might interfere with free emptying of the proximal jejunal loop, as increased intraluminal duodenal pressure predisposes to leakage from the duodenal stump. The same technical points discussed in connection with gastroduodenostomy apply in establishing gastrojejunal anastomosis after gastric resection, namely approximation of the jejunum and the stomach, direction of jejunal loops, length of the proximal jejunal loop, and suturing the transverse mesocolon well back from the anastomosis.

At present, probably no two gastric surgeons would offer an identical group of indications for vagotomy in the treatment of duodenal ulcer. In general the author believes that at this time the operation should be reserved for the exceptional type of patient who has duodenal ulcer.

Gastric retention may occur after transabdominal vagotomy performed for duodenal ulcer even though preoperatively there was no indication of gastric obstruction as shown by clinical or laboratory investigation. Such retention may be severe enough to

require gastroenterostomy. Because of this fact transthoracic vagotomy seldom seems indicated in the treatment of duodenal ulcer. If this viewpoint is accepted transabdominal vagotomy performed in association with gastroenterostomy would constitute the alternative and more desirable procedure. Evaluation of late results of this method of treatment will require the lapse of a number of years. The abdominal approach presents the advantage of permitting direct examination of the lesion and exploration of the entire abdomen. It has the disadvantage until the surgeon has gained considerable experience of making complete resection of all branches of the vagus nerves somewhat less certain.

A prerequisite to the performance of vagotomy is accurate knowledge of the anatomic location and distribution of the fibers of the vagus nerves both above and below the diaphragm. Failure to section all fibers of these nerves can lead only to confusion and unsatisfactory results.

If a transthoracic approach is employed resection of a generous portion of the left eighth rib affords fine exposure. Occurrence of a pathologic process previously in the left side of the thorax adds to the difficulties and in certain cases may make a right-sided approach more desirable. A generous portion (preferably 3 cm. at least) of each vagus nerve should be resected and an effort made to prevent realignment of the nerve ends should regeneration occur.

In the abdominal approach a left-sided incision although it is not essential, aids in obtaining good exposure of the esophagus. Several inches of esophagus should be cleared and extreme care exercised to perform wide resection of all branches of the vagus nerves. A soft rubber catheter or a strip of gauze on which caudal traction is made after it is looped around the esophagogastric junction is helpful in obtaining adequate mobilization and exposure of the esophagus. Mobilization adequate to permit rotation of the esophagus in an arc of at least 180 degrees is essential. All tissue removed should be examined microscopically to aid in the thoroughness of the operation and in the ready recognition of the fibers of the vagus nerves.

Volvulus of the Sigmoid Colon and Its Treatment. CHRISTIAN BRUNSGAARD *Surgery* 1947 33 466.

The author studied 91 patients with volvulus of the sigmoid colon who had been admitted to the Ullevaal Hospital Oslo Norway. Believing that in most cases of sigmoidal volvulus there is torsion of the sigmoid with obstruction of the lumen without strangulation and/or serious circulatory disturbances the author advocated and described a successful nonsurgical method of treatment.

The conditions predisposing to volvulus formation are (1) a long and freely movable sigmoid colon (2) a long and freely movable mesosigmoid and (3) a sigmoid loop whose limbs lie close together. The last condition is encountered in a mesosigmoid with a small fixation angle to the posterior abdominal wall, or may be caused by a shrinking mesosigmoid.

Fig. 1 (Brunsgaard). A, Long sigmoid. B, physiologic volvulus. C, axial torsion of rectal loop of sigmoid in 180 degree volvulus without strangulation of vessels. D, 360 degree volvulus of sigmoid with beginning strangulation. E, 360 degree volvulus with torsion and strangulation.

th. Sixteen of 18 patients who were either operated upon or examined postmortem had striking mesosigmoiditis.

The most moderate form of sigmoidal volvulus is the so-called physiologic volvulus—on with a clockwise asymptomatic torsion of 180 degrees. This usually corrects itself spontaneously and does not exhibit signs of intestinal obstruction. In 180 degree counterclockwise torsion of the sigmoid there occurs intestinal obstruction with circulatory changes. It is believed that volvulus which causes symptoms develops from the asymptomatic 180 degree physiologic volvulus in most cases. The rectal loop which lies behind the colonic loop may be gradually filled with gas and stool because of retention. The heavy rectal loop then changes its position and falls in front of the emptier colonic loop. This torsion of 360 degrees is accomplished. Volvulus of more than 360 degrees occurs rarely.

Fig. 2. Development of torsion stenosis. (From Laurell.)

Groth demonstrated that every torsion of the sigmoid and its mesenteric axis is combined with an axial torsion of the bowel itself. This axial torsion is twice as great as the torsion of the mesentery. Thus the axial torsion is 360 degrees in a 180 degree volvulus. The twisting at the axis of the mesentery and the axial torsion about the axis of the bowel which are characteristic of volvulus cause a mechanical ileus in most cases. When the torsion is moderate a simple type of obstruction occurs. In simple obstruction the intestinal wall is adequately well nourished for the first few days because the sigmoid is most resistant to increasing intestinal pressure.

When the volvulus produces a strangulation ileus, venous stasis occurs. Later depending on the degree of torsion, thrombosis of the mesentery develops and extends. The strangulated intestinal loop may become gangrenous and perforation with resultant peritonitis may occur.

Distention is most marked in instances of a competent ileocecal valve forming a so-called "closed loop." In these cases the small intestine functions normally for some time with resultant moderate loss of fluid and electrolytes. In the more severe cases there is considerable loss of fluid and electrolytes because of the formation of ascites, hemorrhage and vomiting. Exudation in the peritoneal cavity is common. A fecal odor signifies grave changes in the sigmoid colon.

The treatment is either nonoperative or surgical. Spontaneous untwisting of the sigmoid colon may occur when torsion is less than 360 degrees. In torsion of 360 degrees the twisted loop is usually held fast between the anterior and the posterior abdominal wall. Detorsion may occasionally follow a simple or a diagnostic barium enema.

The author has successfully employed proctoscopy and intubation with a rectal tube 60 cm. long and 6 to 10 mm. in diameter 123 times in patients suffering from acute volvulus but without evidence of serious circulatory disturbances in the sigmoid. A sigmoidoscope is introduced to the site of the torsion with the aid of careful inflation. The site of torsion is easily recognized by the characteristic spiral folds. Then a lubricated soft rubber rectal tube is introduced past the site of obstruction without force. Following the passage of the tube there occurs prompt evacuation of flatus and soft feces, and the patient

experiences instant relief. The tube is left in place for 3 to 5 days and is held in place by a suture to the perianal skin. In 9 instances attempts at intubation by proctoscopy were unsuccessful, but without ill effects to the patient. These patients, however, were operated upon immediately after proctoscopy.

Proctoscopy and intubation while effective in the treatment of the acute attack of volvulus, have no effect on the tendency toward recurrence of this lesion. This therapeutic method is therefore not a definitive treatment. Thirty-one of the author's patients had to be readmitted to the hospital and treated two or more times for recurrent volvulus. Only 7 patients with recurrent volvulus were treated by a four stage operation (cecostomy, a Mikulicz procedure, closure of sigmoidostomy and closure of cecostomy).

Recently at the Minnesota University Hospital, Minneapolis, the author observed 2 patients with volvulus of the sigmoid reduced by proctoscopy and intubation. About 2 weeks after the acute volvulus had been reduced these patients underwent a successful primary resection of the sigmoid. As a result of this observation, Brunsgaard now believes that primary resection of the sigmoid colon is superior to the four stage operation employed at the Uppsala Hospital and should be employed when surgery becomes necessary. ROBERT TUNELL, M.D.

Multiples Polyps of the Colon with Malignant Change Involving Colon and Appendix. BRUNO MANN and N. CHANDLER FOOT, Ann. Surg. 1947 126 363

This article consists of a very well documented case history of multiple polyps of the colon, cecum, and vermiform appendix with malignant change involving the colon and the appendix. It is followed by a brief discussion of this unusual condition.

The patient, a 35 year old female, entered the hospital as a very poor surgical risk due to prolonged blood loss. Following intensive preoperative therapy the authors were able to perform a transverse colectomy. This placed the rectum at rest and permitted the removal of polyps from the splenic and hepatic flexures for microscopic study. The result of this operation led to marked improvement in the patient's general condition.

Next a right hemicolectomy and ileotransverse colonic anastomosis were performed. The resected specimen revealed multiple polyps, both malignant and nonmalignant, as well as a well developed carcinoma of the cecum in addition a malignant adenoma of the vermiform appendix was found.

Finally the authors performed a perineal resection of the rectum and lower sigmoid and then the stoma of the transverse colectomy was closed. This entire formidable procedure totaled 118 hospital days.

The authors discuss carcinoma of the appendix and point out the great rarity of this condition and its frequent confusion with carcinoids of the appendix, a neoplasm which histologically resembles carcinoma but acts clinically as a benign tumor.

EDWARD F. LEWISON, M.D.

Carcinoma of the Colon. ARTHUR W. ALLEN, CLAUDE E. WELCH and GORDON A. DONALDSON Ann Surg 1947 126 19

The authors present the data on 105 patients with carcinoma of the colon who were treated since January 1, 1943. This series does not include those with carcinoma of the rectum. Resectability was possible in 95 per cent of the cases.

The period of invalidism following colon resections is dependent on many factors. In spite of the fact that a 2 stage attack is often necessary in the presence of acute obstruction, final resection followed by primary anastomosis has been more satisfactory in the authors' hands than exteriorization procedures. Since the introduction of the Miller Abbott tube and the use of sulfasuxidine and sulfathaladine in the preparation of patients for colon resections, fewer patients have needed cecostomy. In acute complete obstruction and on occasion this procedure is supplemented with complete transverse colostomy. The latter type of decompression is particularly adaptable to extensive inflammatory reaction about the initial lesion. Although rarely necessary in the preparation of patients with cancer of the left colon it is justifiable in doubtful cases and is essential in diverticulitis with obstruction or abscess formation. Complete colostomies are best managed by final excision of all scar tissue and an accurate end-to-end anastomosis with the bowel dropped free into the peritoneal cavity.

The added benefits of chemotherapy have doubtlessly played a role. Carefully controlled anesthesia, blood replacement and better technical surgery have been the chief reasons for better results.

On admission, a patient with suspected cancer of the colon should have the following studies in addition to a careful physical examination and history. A plain film of the abdomen will often reveal the approximate site of the lesion by the gas pattern. This is true particularly when obstruction of any degree is present. If this fails to give a lead one should then proceed with a careful sigmoidoscopy. If the lesion is not visualized a barium enema must be used. The patient's anemia and electrolyte balance are evaluated and proper therapy is instituted to correct them.

Sulfathaladine is as effective in the preparation of the bowel for surgery as is sulfasuxidine. Occasional bleeding from the growth has not been noted when this drug was used but it was observed when sulfasuxidine was in use. The recent finding by Poth that sulfathaladine and penicillin are antagonistic must be borne in mind.

The early favorable changes observed following the removal of an infected obstructing lesion are spectacular. Such aids as blood plasma, and amigen appear more effective postoperatively although the patient's ability to utilize an unobstructed gastrointestinal tract is probably the chief reason for this impression.

Incisions vary to some extent according to previous bowel drainage and the location of the tumor

In primary right colectomy a long right paramedian incision was found more satisfactory as this allowed adequate exposure of the vascular source and nodal spread. Transverse incisions are preferred for the flexures and lesions involving the midcolon. The left colon exposures have been paramedian in cases in which permanent colostomy might prove necessary. Oblique incisions with mesial retraction of the rectus muscle were satisfactory for low sigmoid tumors suitable for end-to-end primary anastomosis. Delayed primary wound closure was practiced with a minimal of wound infection.

Resection of the involved bowel and mesentery was wide on the cephalward side in all instances. In lesions of the left colon the distal segment has been adequate to include any extension of disease into the surrounding tissue. The bowel was divided between thin clamps in the proximal portion early in the procedure.

Instead of isolating the blood vessels to insure viability the disease was removed and the adequacy of the blood supply to the end-to-end anastomoses was determined by visualization. Contact structures were removed with the primary tumor en bloc. These have included all the nonvital organs or parts of them within the abdomen and pelvis. The open method was used in all operations of election.

The rent in the mesentery is carefully closed on both sides when the anastomosis is completely within the peritoneal cavity. If pelvic dissection has been necessary the lateral margin between the bowel and pelvic peritoneum is left open. This obviates the draining of this region through the ischial foras, as formerly practiced. Fistula formation with resultant stenosis of the suture line is thereby avoided. Collections of serum in the hollow of the sacrum may burst into the peritoneal cavity with a transient intraperitoneal reaction. As a rule however seepage from this space is gradual and is adequately handled by the peritoneal cavity.

In suitable patients, dicumarol was used postoperatively to prevent venous thrombosis. However many patients were arteriosclerotic or had other contraindications to the anticoagulant drugs. In these prophylactic superficial femoral vein interruptions were practiced. If the lesion is well above the pelvic floor this procedure can be done before or at the time of the bowel resection. If however pelvic dissection is necessary then the vein interruption should be postponed for 48 hours after operation. There is a transient engorgement of the pelvic veins immediately following femoral vein interruption that definitely increases the blood loss during the pelvic dissection.

The average hospital stay in this series of cases was 35.4 days. The average number of postoperative hospital days was 6. There were 36 cases requiring preliminary bowel drainage or some 2 stage procedure. These averaged 39.9 days in the hospital, while those requiring no second stage averaged 24.8 days.

LEE PULLEN, M.D.

Management of Colostomies Performed for War Injuries. HALL G. HOLLIER and EDWARD F. LEWIS. *Am. J. Surg.* 1947 120 253.

The authors report their wartime experience with 67 colostomies in patients treated by means of definitive surgery in an Army hospital in England and draw a parallel between this experience and the current trends of colon surgery in civilian practice.

Colostomy closure in battle casualties presented many difficulties which are usually not encountered in civilian practice. First among these were the patients with multiple injuries. Such injuries frequently produced superimposed infections, concurrent sepsis, impairment of vital organs, and general debility. Also the initial surgery was performed by surgeons in the forward area under the most difficult and trying conditions. Under these circumstances the exact construction of the colostomy was often not very clear to those who had to do the subsequent reparative work.

An analysis of the collected material reveals the site of injury to be as follows: right colon in 13 cases, transverse colon in 9, left colon in 13, rectosigmoid in 37 and rectum in 7 cases.

Despite the fact that the Army strongly recommended simple exteriorization as the operation of choice for large bowel wounds, the types of colostomy performed are: cecostomy 11, double-barrel-(Mikulicz) 43, loop (exteriorization) 16.

The types of colostomy closure are tabulated by the authors and the preoperative, operative, and postoperative details of technique are outlined and discussed. The results were satisfactory in all but one patient who was evacuated to the Zone of Interior with a persistent fecal fistula.

The authors believe that in colostomy closure an end-to-end (either open or closed) anastomosis is preferable to the spur-crushing technique. In peacetime surgery primary anastomosis of the colon is finding an ever widening circle of acceptance.

Emphasis is placed upon the surgical triad which, in the opinion of the authors, accounted for their satisfactory end results: firstly efficient therapy directed toward improving the patient's general condition prior to operation, secondly the use of chemotherapeutic agents, and lastly the operative care and improvement in surgical technique.

Colostomies, whether they be the result of battle casualties or commonplace conditions of the colon, should be closed at the earliest opportune time.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Biliary Neura (Neurobilia). FRANCISCO J. VIANO and LUDIG G. MOSCA. *Dis. med. B. Afr.* 1947 19 1559.

Biliary Neura is an uncommon occurrence and only 70 cases appeared in the Argentine literature and no more than 300 cases have been reported elsewhere. The authors report the cases of 2 patients 84 and 85 years of age respectively. Both were cured.

In the mechanism of its production in the greater number of cases the calculus proceeds from the gall bladder and migrates through a cholecystoduodenal fistula. In a smaller percentage the migration is through a cholecystogastric fistula, and in a still smaller percentage migration occurs through the common bile duct. Biliary Neura is fundamentally mechanical, although one should also bear in mind the factor of intestinal spasm produced by pressure of the calculus. In the majority of cases these calculi have localized in the terminal end of the ileum, but they can be detained at any other point of the intestinal tract. The calculus may reach the dimensions of 3.5 cm. in width and 7 cm. in length while its shape may be spherical, oval, cylindrical or conical. Spontaneous expulsion of the calculus is possible although infrequent.

The symptoms and signs usually found are as follows: pain is usually localized at the onset in the upper abdomen, right hypochondrium, or epigastrium vomiting at first is gastric, then liquid and bilious, and later black and malodorous, there is stoppage of the intestinal gases and later distention.

The symptoms and signs not usually found are namely: palpable tumor formed by the calculus itself or by an afferent loop of bowel, hematemesis and melena, massive and sudden emptying of the intestine due to the peristaltic stimuli produced by the calculus, right lateral decubitus, disappearance of a palpable gall bladder, migration of pain with the calculus, hiccups, and vomiting of the calculus.

Evolution of the condition is as follows: it begins as a typical hepatic colic or pyloroduodenal stenosis then there is a period of intermittent occlusion, a period of irreversible obstruction, and, last, a period of complications.

Röntgenologically the condition may be diagnosed by direct localization of the calculus or dilated intestinal loops and by verification of the cholecystoduodenal fistula.

In spite of the facts that surgical intervention is simple and that the circulation of the loop of bowel is not seriously affected, biliary Neura has the most severe prognosis and the highest mortality of all intestinal occlusions.

Once the diagnosis is made or suspected, surgical intervention should be immediate. The procedure of choice is enterotomy, the incision being made either over the calculus or directly above or below in the healthy bowel. The incision should be longitudinal, but should be sutured transversely. Anesthesia should be of the local type.

MISCELLANEOUS

The Effect of Heparin upon Intra Abdominal Abscesses in Rabbits. B. M. BLOOR, HUTCH DORTCH, JR., T. H. LEWIS, R. F. KIRKLE, and K. S. SHEPARD. *Ann. Surg.* 1947 76 324.

This is a report of an investigation on the effect of heparin upon the formation and reformation of ad-

hemions in rabbits. The adhesions were formed through a laparotomy incision by freeing and scarifying the antimesenteric border of the appendix. In the series in which heparin was used 15 mgm. of heparin were placed in the abdomen at the time of the operation and a second peritoneal injection of 15 mgm. was given 24 hours after the operation. In some heparin treated rabbits Pitkin's menstruum was used.

The authors conclude from their investigation that the likelihood of developing adhesions was almost as great in the rabbits treated with heparin as in those that were not treated with this drug.

F J LEREMANN JR. M.D.

Retroperitoneal Cysts. H MINOR NICHOLS. *Ann. Surg.* 1947 126 340.

A discussion of the various theories concerning the origin of primary retroperitoneal cysts is presented. The author also reports a case in which there was a palpable mass in the right lower quadrant of the abdomen. A differential diagnosis was

made and the diagnosis of retroperitoneal cyst was made before operation.

Microscopic pathology revealed a diffuse irregular anastomosing series of tiny cleftlike and well formed channels lined by typical endothelial cells. The cyst was also in direct continuity with a large area of typical angiodoma.

An effort has been made to classify these cysts embryologically. In quoting the literature, one author states that there are approximately 500 case reports on omental cysts and only 18 on mesenteric cysts.

The variety of findings microscopically in the wall of the cyst is due to the fact that the tumor arises out of one of the many portions of the wolffian body.

A table is included in which 5 additional case reports not previously summarized are presented.

The diagnosis of retroperitoneal cyst is made by the process of eliminating other possible tumors. The treatment of this condition is entirely surgical.

Five illustrations are also included in the article.

GYNECOLOGY

UTERUS

Investigations into the Uterine Mucosa. Pathologic and Clinical Classification of Metropathia Hemorrhagica. BERTIL FALCOVER. *Acta obst. gynaecol.* 1947 27 S pp. 5

On the basis of endometrial biopsy the author divides cystic glandular hyperplasia into 4 phases as follows:

Group I. Commencing or weakly marked phase. There is an abundance of glands which are crowded and show invagination and dilatation. The cells are high columnar and contain elongated nuclei and localized stromal hyperplasia is present.

Group II. Cystic glandular hyperplasia with the microscopic picture of the classical hyperplasia.

Group III. Cystic glandular hyperplasia with secretory activity. The picture characteristic of hyperplasia but with a varying amount of lutein stimulation which may be noted both in the glands and the stroma.

Group IV. Inactive or atrophic type. The glands are cystic but there is no evidence of glandular activity and the mucosa is thin and atrophic.

The author suggests that the condition may run a cyclic course like that of the menstrual cycle and that there is a definite correlation between the clinical symptoms and the microscopic findings. As to the etiology, he ascribes the major abnormality to ovarian dysfunction from abnormal function of the neuroendocrine system. J. ROBERT WILLIAMS, M.D.

Cervical Cancer: A Disordered Growth Response to Inflammation in the Presence of Estrogen Excess and Nutritional Deficiency. J. LAWRENCE ARZEE. *Am. J. Obst.* 1947 54 365.

During the course of studying vaginal and cervical cytology smears for a diagnosis of uterine cancer it was observed that when cancer was present there was also cytologic evidence of abnormally high endogenous estrogenic activity. Recently a nutritional deficiency of thiamine was frequently found present in cases of abnormal estrogenic cornification. Three cases are presented in detail which demonstrate the combination of poor dietary habits and a low thiamine excretion level, increased cornification in the vaginal and cervical smear (high estrogen content) and the presence of an early cancer of the cervix as shown by both smear and biopsy.

With the hypothesis in mind that cervical cancer is a disordered growth response to inflammation in the presence of estrogen excess and thiamine deficiency 100 cases were studied. Fifty patients had proved cervical cancer and 50 were controls who were in good gynecological health. Cervical smears were studied for estrogenic cornification. Thiamine excretion levels were determined. In a few cases liver function tests and urinary estrogen assays were made.

Some degree of chronic cervicitis is believed to be present in 4 of every 5 adult cervixes. Eighty-two per cent of the patients with cancer had both a high cornification smear and a low thiamine excretion, while none of the controls had this combination. High cornification alone was found in 97 per cent of the cancer patients and in only 62 per cent of the controls. A low thiamine excretion alone was noted in 86 per cent of the patients with cancer and in 10 per cent of the controls. Only 14 per cent of the patients with cancer had a normal thiamine excretion while this excretion was normal in 99 per cent of the controls. A normal or low estrogen cornification smear was found in only 8 per cent of the cancer patients but was noted in 94 per cent of the controls.

A 35 year old patient showing chronic cervicitis and a low thiamine excretion level was placed on stilbestrol in moderate doses over a period of 10 weeks. This was followed by vaginal spotting of blood and cytology tests revealed cells of malignant morphology. Complete excision of the squamocolumnar circle of the cervix was made. Biopsy confirmed the presence of an early carcinoma. The cervix healed and no further change has been noted.

Thus partly by speculation and partly by interpretation of the evidence presented an attempt has been made to correlate infection, excessive tissue estrogens, and nutritional deficiency in the production of cervical carcinoma of the squamous type.

JAMES R. WOLFE, M.D.

Cancer of the Uterus. I. IL NOVAL. *J. Am. Med. Assn.* 1947 135 199.

Uterine cancer is one of the most important of gynecologic problems. No less than 17,151 women in the United States died of this condition in 1944 (the latest year for which complete figures are available). Although great advances have been made much remains to be accomplished.

Pathologists are still in the dark so far as the inciting factors transforming a normal into a malignant cell are concerned. They insist that cancer is a group of diseases, mainly because of the various histologic types found. Probably however a common denominator will some day be uncovered. Heredity certainly plays a role as does chronic irritation, whether the latter be traumatic, inflammatory or hormonal in nature. The traditional teaching is that cervical carcinoma arises in chronic irritative lesions of the cervix. On the other hand carcinoma has been found in a normal appearing cervix. This suggests that in some individuals the genetic influence is so strong that the contributory effect of irritation is unnecessary.

Estrogenic hormones have been indicted as carcinogenic but it is difficult to eliminate *post hoc ergo propter hoc* reasoning in evaluating evidence on this

score. Estrogenic stimulation is of some importance, however since patients with a history of functional menopausal bleeding, a delayed menopause or post menopausal endometrial hyperplasia have a higher than usual incidence of corpus carcinoma. It is advisable to avoid the use of estrogenic substances in women who because of heredity or some other factor have a suspected predisposition to this disease.

The term precancerous has two different meanings (1) lesions chronologically preceding cancer e.g. chronic cervicitis and (2) what has been variously termed as preinvasive carcinoma, intraepithelial carcinoma, carcinoma *in situ* and Bowen's disease of the cervix. Most discussion centers around the malignancy of the latter interpretation of the term. Although the cells concerned are malignant in appearance, invasiveness has not yet occurred. Novak believes that preinvasive carcinoma is the beginning stage of cervical carcinoma and that this stage may be of extremely variable length. During this time the cancer is "benign" and is curable by simple excision. If a single biopsy shows preinvasive cancer further sections of adjacent tissue will often show invasiveness.

In the body of the uterus one may encounter lesions which histologically present all stages between benign hyperplasia and adenocarcinoma. At times it may be almost impossible to differentiate microscopically the benign from the malignant. The author believes that hyperplasia in itself is benign but when it occurs in a postmenopausal woman it predisposes to adenocarcinoma.

There are three more or less recent aids to the diagnosis of uterine cancer. Colposcopic examination as introduced by Hinselmann in 1937 is time-consuming and not very popular. The functional test of Schiller suggests promising points for biopsy. The most heralded and promising diagnostic adjunct is the Papanicolaou smear technique. Its main limitation is the necessity of its interpretation by trained cytologists. As a screening method in presumably normal women it will probably find its greatest field of usefulness. Biopsy and curettage still remain the most dependable means of diagnosis.

Previously in treating cervical carcinoma the gynecologist merely decided (considering both the general and local condition of the patient) whether he was justified in operating. The personal equation was necessarily an important part of the decision. The primary mortality even with the most expert was high. Medical advances such as transfusion, chemotherapy and biophysics were of course not available. Also distressing sequelae as ureteral and bladder injuries with and without fistula formation, were not infrequent. Radium was at first considered merely a palliative measure. It too was occasionally accompanied by serious injury to neighboring structures. Gradually with more intelligent use it became apparent that radium was at least as effective as surgery. Immediate mortality is almost nil.

At present the trend in the therapy of cervical malignancy seems to be toward both radiation and

surgery. Details vary but it is generally conceded that preliminary radiation lessens infection in addition to devitalizing and entrapping cancer cells in fibrous tissue. The surgical procedure may be a true radical Wertheim operation, a panhysterectomy including a large cuff of vaginal mucosa and a great portion of the parametrium or merely a pelvic gland dissection. It is too early to completely evaluate the various methods but it should be emphasized that surgery is applicable to a small number of cases (in only 10 per cent of cases are the lesions of stage I).

Because of the slower extension of the lesion, the less radical operation required the higher cure rate surgery has always played a prominent role in the treatment of corpus carcinoma. At present, preliminary irradiation and then surgery are employed in the majority of clinics. The radiotherapy may be radium x ray or both.

The author concludes that the surest and safest treatment of uterine carcinoma is prevention and lacking this, early diagnosis. Unless the physician takes each case as a personal responsibility and conscientiously directs his patient to the best care available the mortality from uterine cancer will not recede. Education of both layman and physician is vitally necessary. WARREN R. LANE, M.D.

Radium Therapy of Cancer of the Uterine Cervix and of the Fundus. ROBERT E. FRICK, *Surg. Clin. N. America* 1947 27 775

Cancer of the cervix presents too complex a problem for the radiologist alone. The importance of early diagnosis cannot be overstressed. Once a malignant lesion is suspected, the patient is best seen at a clinic. Following a thorough general and pelvic examination, the patient is seen by the surgeon and the radiologist, and the best possible treatment for the individual case is outlined. Co-operation of the clinician, pathologist, radiologist and surgeon is essential.

The plan of radium treatment at the Mayo Clinic is defined as an intensive broken dose method. A 50 mgm. platinum filtered tube is the unit of treatment and the average advanced lesion receives a total dose of 7,000 to 8,000 milligram hours throughout the entire birth canal in approximately eight applications in a period of 3 weeks. At the start treatments are applied twice a week and more rapidly thereafter the exact interval depending on the visible response of the tumor.

The main principles of treatment are (1) homogeneous irradiation of the entire birth canal by fairly short repeated treatments (2) avoidance of trauma in probing the canal and inserting the tube (3) use of the knee-chest position to secure adequate exposure and to avoid trauma during the necessary manipulations, (4) use of adequate gauze packing above the tube to increase the distance of the intestinal wall from the element, and (5) adequate follow-up studies of each patient over many years.

After the radium treatments, a supplementary course of roentgen therapy is given at 200 kilovolts

and with 550 roentgens measured in air to each of four fields in the hope of sterilizing the parametrial regions. In stage 3 or 4 lesions, the course of roentgen therapy is repeated 3 months later.

A review of several hundred cases in which radium treatment was used showed that patients with stage 1 lesions had a 69.5 per cent 5 year survival rate, stage 2 60.5 per cent stage 3 50.7 per cent and stage 4 6.5 per cent. These results concerned patients not treated before admission. Results in the

modified cases in which the patient came to the Clinic after some treatment elsewhere were less satisfactory. This modified group formed a large portion—415 patients of the total of 1,491. Five year arrest of the cancer in stages 1, 2, 3 and 4 was 100 per cent (only 4 cases), 56 per cent, 10.8 per cent and 4 per cent respectively, of the patients treated. The 5 year survival rate of all patients primary and modified, with cancer of all stages was 36.8 per cent of the 1,352 patients traced.

During the first course of treatment the main complications encountered in 3 or 6 per cent of patients have been due to spread of infection or to hemorrhage. All cervical cancers are infected when first seen the topical application of bactericidal agents during the course of treatment clears up the majority of localized infections. Occasionally however pelvic cellulitis spreads, eventuating in a pelvis abscess or peritonitis. Cancer therapy is then stopped and measures are taken against the infection. The recent development of sulfonamide drugs and penicillin has undoubtedly cut down the treatment mortality rate even though in former years this has averaged only 1 per cent. Once the spread of infection has been halted and the elevated temperature of the patient has returned to normal cancer therapy may be resumed sometimes after a rest period of 3 or 4 weeks.

In treating hemorrhage associated with cervical carcinoma, tight packing of the vagina with gauze every other day while proceeding with radium treatments will control the condition. After several radium treatments a few days apart enough connective tissue forms to stop the excessive bleeding. Hemorrhage is a serious complication. Some patients when first seen are so exsanguinated that transfusions and other supportive measures are necessary before cancer treatment can be started. Anemic tissues also heal more slowly than normal tissues.

Complications which appear during subsequent visits of the patient are usually due to spread of the malignant lesion, uncontrolled by the previous radium therapy. They are usually due to lateral parametrial spread or to metastasis. One ureter may be occluded by the presence of cancer in the region of the broad ligament, and result in hydronephrosis and hydronephrosis and finally in a nonfunctioning kidney. When both ureters are occluded death from uremia ensues and is the most common cause of death in uncontrolled cervical cancer. When one kidney is functionless palliative radium therapy may delay the fatal outcome. Other late complications are rectovaginal and vesicovaginal fistulas. Occasionally de-

layed healing of tissues following radium therapy results in the formation of craters at the site of the cervix covered with infected slough. The application of radon ointment to these craters has appeared to promote healing in several instances. Very occasionally pyometra may be found dilatation of the cervix with a rubber catheter and irrigation of the uterus with antiseptic solutions usually is effective.

These late complications are often seen in stage 4 lesions before any radium therapy has been given and they should be thoroughly studied. Whenever excessive pelvic infiltration is determined, excretory urograms and blood urea determinations should be carried out. Limited radium therapy usually affords some palliation in the presence of these late complications.

Because of the nature of cancer of the body of the uterus, characterized by slow growth and delayed metastasis surgical removal of the uterus usually achieves a cure. Complete hysterectomy not as radical or difficult an operation as the Wertheim hysterectomy successfully eradicates the cancer.

Radiologists are interested in two groups of cases of this form of malignant lesion: those in which the lesion has extended widely before the diagnosis was established so that surgical treatment is no longer feasible (stages 3 and 4), and those in which the lesion is still small but the patients themselves are poor operative risks because of other coexisting serious illnesses.

The underlying principle of treating cancer of the corpus uteri is as with cancer of the cervix homogeneous irradiation of the entire birth canal employing the intensive broken dose method. Following the diagnostic curettage, two 50 millicurie radon tubes in tandem formation filtered with 0.5 mm. of silver and enclosed in a 1 mm. brass tube on a long copper wire are introduced to the depth of the uterine canal for 24 hours. With the patient in the knee-chest position the applicator can be readily introduced with little trauma. The radon tubes fit into a narrow brass applicator when radon is not available. Two 50 mgm. tubes filtered with 5 mm. of platinum in a brass capsule of 0.3 mm. wall thickness are used. The wire is wound up in the gauze which is packed above the cervix filling the vagina and elevating the perirectal tissues to a safe distance. About a week later a second tandem is used this time in the midportion of the uterus. It is placed by introducing the applicator to the depth of the uterus, then withdrawing it about 3 cm. and bending the wire where it emerges from the cervix. Again the two 50 millicurie radon tubes are left for 24 hours. If the uterus is very large three tandems may be employed in different positions but with some overlapping thus the interior of the uterine corpus receives from 4,800 to 7,200 millicurie hours in a period of 3 weeks. With two intracavitary tandems the more usual treatment, at 1 cm. depth from the midline of the tubes the dosage varies from 5,200 gamma roentgen at one end of the applicator to between 11,000 and 21,000 gamma roentgens at the midpoint of the applicator depending on the

amount of overlapping. In addition to the intra-uterine treatments, a deep cervical canal treatment of 50 mgm. filtered with 1 mm. of platinum is placed for 14 hours and two or three vaginal applications of 50 mgm. each filtered with 1 mm. of platinum and 1 cm. of hard rubber are placed across the face of the cervix and in the right and left fornix on different days for 14 hours each.

The foregoing is a condensed description of a complete treatment given when the lesion appears to be small and cure seems possible. It is given in a period of 3 weeks more than one intrauterine treatment a week is never applied. Cervical and vaginal treatments may be given in the interval. The radium treatment is followed by a course of high voltage roentgen treatment 200 kv. 30 ma. 50 cm. distance, large fields, 550 roentgens per field for four to six fields around the pelvis, one field a day. The roentgen therapy may be repeated 3 months later in the more extensive cases.

In extensive lesions limited radium therapy designed for palliation only consists of the use of only one tandem and perhaps vaginal applications to shrink the growth and reduce pressure.

The results of radium treatment of cancer of the corpus uteri have been surprisingly good. Of course, the 5 year salvage depends on the percentage of stage 1 and stage 2 lesions referred for radium therapy. At the Mayo Clinic, the 5 year survival rate mounted from 12.63 per cent to 39 per cent when a greater percentage of less advanced lesions were treated. Study of the microscopic grade of the lesions yielded an interesting prognostic factor. Whereas in carcinoma of the cervix in which the treatment can be individualized the survival rate remained essentially the same for the different microscopic grades treated in cancer of the uterine corpus, in which therapy is rather standardized the grade was a very important prognostic factor. The 5 year survival rates varied from 79 per cent in grade 1 to 12 per cent in grade 4.

EXTERNAL GENITALIA

Relationship of the Vagina to the Adjacent Organs
In Reconstructive Surgery. A Histologic Study
J. V. Ricci, J. R. Lina, C. H. Tuom and W. L. Krom
Am. J. Surg., 1947 74 387

Specimens consisting of the perineal body, anal canal, rectum, vagina, urethra, bladder, cervix and fundus were removed en masse from 23 cadavers (4 fetuses, 3 infants, and 15 adults). After fixation, some of these specimens were subjected to serial cross-sections, some to serial sagittal sections, and others to both following an accurate longitudinal bissection. The purpose of the investigation has been to demonstrate microscopically all the tissues between the mucosa of the vagina throughout its entire length and the mucosa of all the juxtaposed organs such as the anal canal, the rectum, the urethra, and the bladder. Further this investigation has as its purpose to prove or disprove the presence of a fascia

variously designated isolated and utilized for reconstruction of the relaxed, sagging and sacculating anterior and posterior vaginal walls. As a basis for discussion and classification of tissues, a fascia is considered a sheet of compact connective tissue of variable thickness completely devoid of muscle substance and possessing tensile strength for supportive and reconstructive purposes.

There is a complete fusion of the fibromuscular elastic wall of the vagina and the juxtaposed wall of the urethra throughout its entire length from the external urethral orifice to the trigone of the bladder. These two walls are closely integrated by interweaving strands of collagenous connective tissue and elastic fibers. No line of separation is present. But the portion closer to the urethral canal is more vascular than the portion closer to the vaginal canal. Between the urethra and the vagina there is neither cleavage plane, areolar zone nor any substance remotely resembling a sheetlike structure of compact connective tissue, i.e., a fascia.

There is a definite line of separation, a cleavage plane, an areolar zone between the anterior vaginal wall and the juxtaposed wall of the bladder from the vesicouterine fold to the trigone. This line of separation is marked by the presence of loose shreds of areolar fibers. There is no substance between the bladder and the anterior vaginal wall which in any way resembles a sheetlike structure of compact connective tissue, i.e., a fascia.

There is a complete fusion of the fibromuscular elastic structure of the outermost vaginal wall as it comes in contact with the short perineoanal canal. The point of fusion ends approximately where the anal canal continues as the rectum. Between this portion of the vagina and the perineoanal canal there is no cleavage plane, no areolar zone, no substance which in any way resembles a sheetlike structure of compact connective tissue, i.e., fascia.

There is a definite line of separation, a cleavage plane, an areolar zone between the posterior vaginal wall and the juxtaposed rectal wall beginning approximately at the anorectal junction and ending where the rectum comes in contact with the col-de-sac peritoneal reflection. The separation of these two organs is marked by the presence of loose shreds of areolar fibers. Between the posterior vaginal wall and the rectum, there is no substance which in any way resembles a sheetlike structure of compact connective tissue, i.e., a fascia.

The vaginal wall is a fibroelastic muscular structure with abundant connective tissue fibers. The muscular fibers are not separated into two distinct layers of inner circular and outer longitudinal but consist of circular and longitudinal fibers of irregular distribution. It is only in the midportion of the vagina that the circular fibers give a suggestive pattern of a definite arrangement. In the same location both circular and longitudinal fibers are "stouter" particularly in the lateral and posterior portions. These muscle fibers become lost in that portion of the vaginal wall forming the fornices and the cervix.

Inferiorly they also become lost around the introitus of the vagina and perineal body. The vascular components of the vaginal wall are abundant in the midportion and in the lateral portions of the vagina.

The mucosa of the anorectum is loosely attached by its submucosa to the muscles at the anorectal junction are ultimately integrated into the perineal body. Above the perineal body the inner and outer muscular layer of the rectum are separated by an areolar tissue as loose in texture as the submucosa and as the areolar zone lying between the rectum and vagina. The muscularis of the rectum is extremely thin becoming increasingly stout and compact as the rectosigmoid is reached.

The absence of an areolar cleavage plane between the anterior vaginal wall and the wall of the urethra, and the presence of a complete fusion of the fibromusculoelastic structure of these two organs necessitates blunt dissection of the fibromusculoelastic structure to effect a separation between the urethra and the vagina. Separation of the fused layers of tissue of these two organs invariably leads to a manageable but unavoidable general ooze.

The presence of a definite line of separation, an avascular areolar cleavage plane between the fibromusculoelastic vaginal wall and the bladder wall facilitates a clean cut anatomic and bloodless separation of these two organs if the operator enters the true avascular vesicovaginal space.

The absence of an areolar cleavage plane between the outermost portion of the posterior vaginal wall and the perineoanal canal and the presence of a complete fusion of these structures necessitates blunt dissection to effect a separation of this portion of the vagina. Separation of the fused layers of tissue of

these organs leads to manageable but unavoidable general ooze and even brisk bleeding.

The presence of a definite line of separation, an avascular areolar cleavage plane between the posterior vaginal wall and the rectal wall, beginning approximately at the anorectal junction and ending where the vaginal wall fuses with the cervix and the rectum comes in contact with the cul-de-sac peritoneal reflections facilitates a clean cut anatomic and bloodless separation of the rectum and the vagina provided the operator enters the true avascular rectovaginal space.

There is no microscopic evidence whatsoever to substantiate belief in the existence of a so-called "fascia" between the urethra and the vagina, between the bladder and the vagina, between the perineoanal canal and the vagina, and between the rectum and the vagina predicated on the basic concept that a fascia is a connective tissue sheet of variable thickness and possessing tensile strength. Such designations as urethrovaginal, vesicovaginal, pubocervical, pubovesicocervical, uteropubic, and rectovaginal fascias are gynecological misconceptions. And to dismiss the argument merely on the basis of a variation in terminology is a *reductio ad absurdum*. The gynecologist who "succeeds" in isolating these "indispensable fascias" for reconstructive purposes has split the fibromusculoelastic vaginal wall into two layers the innermost of which he erroneously designates as a fascia. Since the microscopy of the area in question shows none of these mentioned fascias, these designations should be stricken from the literature dealing with gynecological anatomy of the pelvis and that dealing with reconstructive vaginal plastic surgery.

CHARLES BASOR, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

A Rare Ectopic Pregnancy in the Left Cornu of the Uterus. ADOLF WIST *Ann. chir. gyn. fenn.*, 1947 36: 139.

The author reports a case in which a preoperative diagnosis of extrauterine pregnancy, a postoperative diagnosis of intertubal pregnancy, and a microscopic diagnosis of pregnancy developing in epithelial passages outside the tube in the cornu of the uterus was made.

The history and findings were typical of an early ruptured ectopic pregnancy with the acute symptoms developing 45 days after the last normal menstrual period. At operation a defect was present in the left cornu of the uterus through which a small piece of placenta was presenting. The left cornu and tube were resected and the entire specimen was sectioned serially.

The tube showed no evidence of inflammation or endometriosis, nor was there a decidual reaction present. The cavity containing the embryo was situated deep in the muscle of the cornu and as it was traced a number of ductules lined by a tubal type of epithelium were present in the surrounding muscle. No communication between the tube or uterus and these ductules could be demonstrated.

The author discussed the various possibilities as to how the fertilized ovum reached its site, including the possibility of erosion from the uterine cavity, endometriosis, and salpingitis isthmica nodosa, and discarded them all on the basis of his microscopic findings. He concluded that the ovum had presumably passed to its final site along passages lined with tubal epithelium and opening into the proximal third of the infundibular part of the tube. He did not demonstrate these connections. Perhaps this could have been a pregnancy which had reached its final site through an accessory tube. There were no sections made of the associated broad ligament.

GEORGE B. BRADSHAW, M.D.

Studies in Rh Isoimmunization in Pregnancy MILTON S. SACKS, WILLIAM J. KUHNS, and ELSA F. JAEHL *Am. J. Obst.* 1947 54: 400

Since August, 1945 the Rh typing laboratory of the University of Maryland School of Medicine Baltimore has made observations on 12,875 patients in 1 year. 1,635 of the patients were Rh-negative, and among these there were 96 isoimmunized women.

Erythroblastosis fetalis occurred in the offspring of 53 or 67.1 per cent of 79 isoimmunized women. Erythroblastosis fetalis was absent in the infants of 26 or 32.9 per cent of this group. The fact was emphasized that the presence of Rh-isoimmunization was not necessarily synonymous with hemolytic disease in the offspring. This disease occurred once among 215 deliveries, an incidence of 0.46 per cent in the total group of 12,875 women studied.

Of the 96 isoimmunized women 10 were primigravidae, and 86 multigravidae. Six of the 10 primigravidae had a definite history of previous transfusions. In 48.8 per cent of the multigravidae, the initial evidence of isoimmunization occurred with the second pregnancy. Initial isoimmunization in the remaining 51.2 per cent was scattered from the third to the eleventh pregnancy.

Fifty-five patients were studied in an effort to correlate parturient antibody titers with the outcome of pregnancy. When serum agglutination titers exceeded 10 units a significant infant mortality was noted. In 40 patients who were studied by the plasma agglutination technique, significant infant mortality occurred only when the maternal titers were somewhat higher. A distinct correlation between the maternal serum titers and neonatal disease was demonstrated in most instances. The duration of the existence of the parturient isoimmunized state, although of significance, was believed to be less important prognostically than the antibody titer.

The influence of labor on the antibody titer was studied in 19 patients. Eleven, or 57.8 per cent showed a significant rise in titer.

Eighteen patients who were observed from 1 to 60 months post partum were demonstrated to still have antibodies in the circulating blood. The significance of this fact for transfusion and subsequent pregnancies is noted. JOHN R. WOLFF, M.D.

Toxic Complications of Pregnancy in Gorgas Hospital, Panama Canal Zone, 1931-1945 NAYD S. SCHENKMAN, GEORGE A. CULVER, and R. A. STEVENSON *Am. J. Obst.*, 1947 54: 428.

The present investigation is an analysis of the 10,000 pregnant patients delivered at the Gorgas Hospital in the Panama Canal Zone between 1931 and 1945. The records of the Gorgas Hospital afford an unusual opportunity to evaluate the influence of race, economic conditions, and a tropical climate on pregnancies under good prenatal care.

Three distinct groups of peoples populate the Canal Zone. There are the Panamanians, who are divided into the silver and the gold groups. The silver group is composed of the West Indian negroes and Panamanians whose income is limited by low fixed standards; their housing is crowded, families are large and life for them is a continuous economic struggle. The gold patients are Panamanians who are employed by the government and have a standard of living comparable to the Americans. The third group are the white Americans who have migrated to this area.

There has been a marked increase in the incidence of eclampsia in the Canal Zone during this period. This increase is a real one and is not due to changed standards of medical diagnosis. It is common to all the groups of people. No significant seasonal variations could be found.

There is a markedly higher incidence of eclampsia in negroes in Panama which cannot be adequately accounted for by racial dietary therapeutic or climatic factors. It is believed that adverse social and psychological factors affecting the negroes to a greater degree than the other population groups may be an important influence. *JOHN R. WOLFE M.D.*

Further Observations on the Use of the Neutral Diet and Hydration in the Treatment of Toxemias of Late Pregnancy *RUSSELL R. DE ALVARADO M. J. Obst. 1947 54 445*

Patients with toxemia in late pregnancy are generally best managed in a conservative fashion. The essentials of this conservative management consist of hospitalization bed rest hydration neutral diet and ammonium chloride. The object of treatment is to return the involved tissues and organs to and to maintain them in, as nearly a physiologic capacity as possible. The management of these patients is designed to treat the toxic manifestations already demonstrated and prevent additional ones.

It is imperative that treatment be instituted early in order to prevent progression of seemingly insignificant findings as well as to forestall latent sequelae. Bed rest and hospitalization are essential preliminaries for treatment. The neutral diet consists of foods which yield an equal amount of acid and alkaline ash to which are added certain foods which yield an ash with no chemical reaction. The term "neutral diet" implies that the diet is salt free and sodium poor. The average diet contains about 2,000 calories daily. The protein content is maintained at from 85 to 100 gm. daily. Fluids are forced to a level sufficiently high to produce urinary excretion approximately equal to that of a normal individual. Fluids are supplied by mouth parenterally or by both routes if necessary in order to insure a minimum daily urinary output of 2,000 c.c. Frequently a daily minimum fluid intake of 4,000 c.c. is necessary to obtain a normal water balance. Ammonium chloride is administered to release the sodium ion from the tissues and to release the intercellular fluid retained by the sodium. It is given in gelatin capsules in order to insure complete absorption. The average dose is 45 gr. 3 times daily which is continued for 4 days. Sedation is used when needed.

When conservative methods fail to control pregnancy toxemia termination of the pregnancy is effected by the most conservative means suited to the particular individual. The indications for cesarean section in toxemia patients should be essentially the same as in patients without toxemia.

JOHN R. WOLFE M.D.

Chronic Hypertension and Pregnancy *F. J. BAOWKZ. Brit. M. J. 1947 53.*

Of all cases of toxemia of pregnancy 15 per cent occur in women who before pregnancy begin are the subject of chronic hypertensive vascular disease. These cases are differentiated from the much more common pre-eclamptic toxemias (70% of toxemias)

and the much rarer chronic glomerular nephritis in pregnancy (5%).

The standard of normal blood pressure is taken by the author to be 120/80, although other authorities have taken as normal an upper limit of 140/90. As a rule blood pressure in normal pregnancies is lower than in the nonpregnant adult particularly the diastolic pressure and there is a greater pulse pressure. Other considerations of blood pressure are that (1) it does not rise with age in normal persons but does in the potentially hypertensive (2) a 10 year elevation of blood pressure above 120/80 is pathological (3) transient rises in the blood pressure should be ignored (4) 40 per cent of the population of the United States is actually potentially hypertensive.

In separating patients in the chronic hypertensive group from those in the pre-eclamptic group, the author places in the former group those patients in whom hypertension is discovered before the twentieth week of gestation and in the latter those who are found to have hypertension after the 20 week border line. He notes a definite familial tendency of hypertension in the former group not in the latter. Clinically the woman with chronic hypertension is somewhat older than normal (average age 30.3 years) she feels well and has no edema albuminuria, or impaired renal function her previous pregnancy has generally ended in stillbirth or abortion. During the second 3 months of gestation her blood pressure falls in a certain number of cases (40% in the author's series) a fact important in differentiating this condition from pre-eclamptic toxemia. However the pressure rises again during the last 3 months, generally at the twenty-fifth week or later (54% of cases) but the mechanism of this last rise is not understood.

Clinical experience shows that when the blood pressure reaches 160 mm. systolic, albumin usually appears in the urine and the fetus is apt to die in utero (17.5%). The albuminuria is not itself the cause of fetal death, nor is there a renal toxin involved rather it is thought that both the albuminuria and fetal death are due to the same cause, i.e. vascular spasm which causes albuminuria in the kidney and anoxia and injury to the vessel walls of the uterus and terminates in concealed hemorrhage.

Pregnancy should be terminated early if renal function studies show decided deficiency or if there is definite retinal arteriosclerosis, exudates, papilledema or if there is persistent albuminuria even with albuminuria alone which is noted before the twentieth week, intrauterine death is almost inevitable. The patient's reaction to rest is a guide to the continuation of pregnancy—if her pressure remains at 150/100 or over the outlook toward a favorable outcome is doubtful but should it fall one may be optimistic. Every clinical therapeutic effort should be made to keep the blood pressure below the critical level of 160 mm. systolic, and this is accomplished by bed rest in the hospital and sedation. The use of potassium thiocyanate is suggested for the high levels but its results have not been satisfactory according to the author. The author emphasizes, how

ever that papilledema with or without retinal exudates is a primary indication for therapeutic abortion.

A natural delivery may be allowed if there is no serious exacerbation or if pre-eclamptic toxemia does not appear. If intervention is to be carried out it is well to wait until about the thirty-seventh week (counted from the first day of the last menstrual period) when the fetus is viable and has a better chance of survival than if it is left in the uterus until term. Although cesarean section should generally be employed in cases of prematurity induction and birth through the natural passages has its place in handling these cases.

The outlook for the child bears a definite relation to the height of the blood pressure at the start of pregnancy, the fetal mortality is around 60 per cent when the blood pressure is over 150/100 in the mother. However if the blood pressure falls during the second trimester there is an excellent chance that a healthy child will be born at term.

Pregnancies exert no lasting deleterious effect on the patient with hypertension although there is a much greater risk that eclampsia or pre-eclamptic toxemia may develop in the hypertensive patient. Although the patient does not actually benefit from pregnancy pregnancy is not injurious provided the patient survives the immediate risks of the parturient nor does pregnancy seem to cause any permanent aggravation of hypertension.

Comparative statistics by the author show that there is no significant difference between blood pressures in nulliparous and parous women in any age group. In fact, neither pre-eclamptic toxemia nor eclampsia per se cause chronic hypertension or bring out a latent hypertension earlier than it otherwise would have appeared.

PHILIP B. CHASE, M.D.

Pollomyelitis in Pregnancy. ANTERO SETÄLÄ. *Ann. Chir. Gyn. Fenn.* 1947 36 117

The author reviews the Scandinavian literature on acute pollomyelitis in pregnancy and lists 87 cases. He adds 15 of his own from Finland and notes that the incidence of pollomyelitis has increased in the older age groups. Pollomyelitis was found to be more prevalent among males than among females, but there were more women aged 20 to 40 than men among the reported cases for the entire country.

The expected incidence of pollomyelitis in pregnancy in the city of Helsinki based on the birth rate and the total number of cases is calculated and the figures would predict an incidence of from 2 to 3 cases. Actually 6 cases were discovered. A survey of the other reported cases based on similar statistics revealed that the actual incidence was three times that which was expected.

The pooled statistics indicated that most women with pollomyelitis in pregnancy suffered from the type that is associated with paresis. No difference could be observed in predisposition to the disease in the different stages of pregnancy. The prognosis was variable with the different authors reporting

and of 61 cases in which the prognosis was discussed there were 14 maternal deaths. In Setälä's series of 15 cases there were 5 deaths 4 of these occurring in the latter half of pregnancy.

Because of the small number of cases, no definite conclusions could be reached as to the course of labor and the delivery but it seemed to the author that the duration of the first stage of labor was not prolonged, and that only in patients with paresis of the abdominal muscles was the second stage prolonged beyond the usual expected duration. Post partum hemorrhage did not occur in any of the cases in this series.

The intrauterine development of the babies appeared to be normal and although the question as to whether the fetus can contract the disease in its intrauterine life is undecided none of the babies had symptoms at birth, nor did they show evidence of it in the cases which were followed.

GEORGE B. BRADBURN, M.D.

Pregnancy Complicating Tuberculosis. C. J. BARON, J. A. FIDIO and L. H. HETHERINGTON. *Am. J. Obst.*, 1947 54 475

The incidence of tuberculosis complicated by pregnancy at the Elizabeth Steel Magee Hospital Pittsburgh Pennsylvania is 0.35 per cent. A review of 62 cases of tuberculous patients followed for a 5 to 15 year period is presented.

Of these 62 patients 33.8 per cent are now dead and of the latter 30.6 per cent died of tuberculosis.

Of those in whom the pregnancy was interrupted by abortion within the first 3 months, 38 per cent are now dead.

Of the 62 patients 61.5 per cent had moderately advanced or far advanced tuberculosis and 44.8 per cent of the latter are now dead. All types of delivery including therapeutic abortion were used. Of the patients subjected to cesarean section in order to terminate the pregnancy 36.3 per cent are now dead of tuberculosis. The mortality for the patients who had spontaneous deliveries was 19.8 per cent.

The best results in this survey were obtained in those patients who delivered spontaneously regard less of the extent of the tuberculosis.

JOHN R. WOLFF, M.D.

LABOR AND ITS COMPLICATIONS

Elective Induction of Labor. R. M. GRIER. *Am. J. Obst.* 1947 54 511

The elective induction of labor has long been a subject of much controversy. Some regard it as needless and vicious. Others state that the membranes may be ruptured with impunity. In the past 10 years labor has been induced by choice in 1,353 or 12.9 per cent, of the women delivered at the Evanston Hospital Evanston Illinois.

The precipitation of imminent labor by rupture of the membranes can be very successful. The proper selection of cases is most important. The criteria for this proper selection are (1) there should be no

There is a markedly higher incidence of eclampsia in negroes in Panama which cannot be as adequately accounted for by racial dietary therapeutic or climatic factors. It is believed that adverse social and psychological factors affecting the negroes to a greater degree than the other population groups may be an important influence. JOHN R. WOLFF MD

Further Observations on the Use of the Neutral Diet and Hydration in the Treatment of Toxemias of Late Pregnancy RUSSELL R. DE ALVARES
Am J Obst 1947 54 445

Patients with toxemia in late pregnancy are generally best managed in a conservative fashion. The essentials of this conservative management consist of hospitalization, bed rest, hydration, neutral diet, and ammonium chloride. The object of treatment is to return the involved tissues and organs to and to maintain them in as nearly a physiologic capacity as possible. The management of these patients is designed to treat the toxic manifestations already demonstrated and prevent additional ones.

It is imperative that treatment be instituted early in order to prevent progression of seemingly insignificant findings as well as to forestall latent sequelae. Bed rest and hospitalization are essential preliminaries for treatment. The neutral diet consists of foods which yield an equal amount of acid and alkaline to which are added certain foods which yield an ash with no chemical reaction. The term "neutral diet" implies that the diet is salt free and sodium poor. The average diet contains about 2,500 calories daily. The protein content is maintained at from 85 to 100 gm daily. Fluids are forced to a level sufficiently high to produce urinary excretion approximately equal to that of a normal individual. Fluids are supplied by mouth, parenterally or by both routes if necessary in order to insure a minimum daily urinary output of 2,000 c.c. Frequently a daily minimum fluid intake of 4,000 c.c. is necessary to obtain a normal water balance. Ammonium chloride is administered to release the sodium ion from the tissues and to release the intercellular fluid retained by the sodium. It is given in gelatin capsules in order to insure complete absorption. The average dose is 45 gr 3 times daily which is continued for 4 days. Sedation is used when needed.

When conservative methods fail to control pregnancy toxemia, termination of the pregnancy is effected by the most conservative means suited to the particular individual. The indications for cesarean section in toxemia patients should be essentially the same as in patients without toxemia.

JOHN R. WOLFF MD

Chronic Hypertension and Pregnancy F. J. BAOWE
Brit. M J 1947 283.

Of all cases of toxemia of pregnancy 25 per cent occur in women who before pregnancy begin are the subject of chronic hypertensive vascular disease. These cases are differentiated from the much more common pre-eclamptic toxemias (70% of toxemias)

and the much rarer chronic glomerular nephritis in pregnancy (5%).

The standard of normal blood pressure taken by the author to be 120/80 although other authorities have taken as normal an upper limit of 140/90. As a rule, blood pressure in normal pregnancies is lower than in the nonpregnant adult, particularly the diastolic pressure and there is a greater pulse pressure. Other considerations of blood pressure are that (1) it does not rise with age in normal persons but does in the potentially hypertensive (2) a 10 year elevation of blood pressure above 120/80 is pathological (3) transient rises in the blood pressure should be ignored (4) 40 per cent of the population of the United States is actually potentially hypertensive.

In separating patients in the chronic hypertensive group from those in the pre-eclamptic group, the author places in the former group those patients in whom hypertension is discovered before the twentieth week of gestation and in the latter those who are found to have hypertension after the 20 week border line. He notes a definite familial tendency of hypertension in the former group, not in the latter. Clinically the woman with chronic hypertension is somewhat older than normal (average age 30.3 years), she feels well and has no edema, albuminuria or impaired renal function, her previous pregnancy has generally ended in stillbirth or abortion. During the second 3 months of gestation her blood pressure falls in a certain number of cases (40% in the author's series) a fact important in differentiating this condition from pre-eclamptic toxemia. However the pressure rises again during the last 3 months, generally at the twenty fifth week or later (54% of cases) but the mechanism of this last rise is not understood.

Clinical experience shows that when the blood pressure reaches 160 mm. systolic, albumin usually appears in the urine and the fetus is apt to die in utero (17.8%). The albuminuria is in itself the cause of fetal death, nor is there a renal toxin involved rather it is thought that both the albuminuria and fetal death are due to the same cause, i.e., vascular spasm which causes albuminuria in the kidney and anoxia and injury to the vessel walls of the uterus and terminates in concealed hemorrhage.

Pregnancy should be terminated early if renal function studies show decided deficiency or if there is definite retinal arteriosclerosis, exudates, papilledema or if there is persistent albuminuria even with albuminuria alone which is noted before the twentieth week. Intrauterine death is almost inevitable. The patient's reaction to rest is a guide to the continuation of pregnancy—if her pressure remains at 150/100 or over the outlook toward a favorable outcome is doubtful but should it fall one may be optimistic. Every clinical therapeutic effort should be made to keep the blood pressure below the critical level of 160 mm. systolic, and this is accomplished by bed rest in the hospital and sedation. The use of potassium thiocyanate is suggested for the high level but its results have not been satisfactory according to the author. The author emphasizes, how-

ever that papilledema with or without retinal exudates is a primary indication for therapeutic abortion.

A natural delivery may be allowed if there is no serious exacerbation or if pre-eclamptic toxemia does not appear. If intervention is to be carried out it is well to wait until about the thirty-seventh week (counted from the first day of the last menstrual period) when the fetus is viable and has a better chance of survival than if it is left in the uterus until term. Although cesarean section should generally be employed in cases of prematurity induction and birth through the natural passages has its place in handling these cases.

The outlook for the child bears a definite relation to the height of the blood pressure at the start of pregnancy, the fetal mortality is around 60 per cent when the blood pressure is over 150/100 in the mother. However if the blood pressure falls during the second trimester there is an excellent chance that a healthy child will be born at term.

Pregnancies exert no lasting deleterious effect on the patient with hypertension although there is a much greater risk that eclampsia or pre-eclamptic toxemia may develop in the hypertensive patient. Although the patient does not actually benefit from pregnancy pregnancy is not injurious provided the patient survives the immediate risks of the parturient nor does pregnancy seem to cause any permanent aggravation of hypertension.

Comparative statistics by the author show that there is no significant difference between blood pressures in nulliparous and parous women in any age group. In fact, neither pre-eclamptic toxemia nor eclampsia per se cause chronic hypertension or bring out a latent hypertension earlier than it otherwise would have appeared.

LABOR AND ITS COMPLICATIONS

Elective Induction of Labor R. M. GRIER. *Am. J. Obst.* 1947 54 511

The elective induction of labor has long been a subject of much controversy. Some regard it as middlesome and vicious. Others state that the membranes may be ruptured with impunity. In the past 10 years labor has been induced by choice in 1,353 or 12.9 per cent of the women delivered at the Evanston Hospital Evanston, Illinois.

The precipitation of imminent labor by rupture of the membranes can be very successful. The proper selection of cases is most important. The criteria for this proper selection are (1) there should be no

cephalopelvic disproportion (2) the baby should be mature and preferably present by the vertex (3) the fetal head should be engaged or dipping well into the pelvis, (4) the cervix should be soft partially effaced and dilated to at least 1 cm.

The use of a dressing forceps rather than a sharp pointed perforator and its guidance through the vagina with a gloved finger in the rectum is the recommended method of rupturing the membranes to induce labor. The use of quinine and castor oil is potentially harmful often inefficient and certainly unpleasant. Calcium gluconate given intravenously has seemed to be a definite aid in producing normal and efficient uterine contractions. Pituitrin in more than 1 minim doses is not necessary. The usual technique of induction is to give a hot soapsuds enema followed by 10 c.c. of 10 per cent calcium gluconate solution given intravenously. Within 2 hours the membranes are ruptured artificially as described. If labor does not ensue within 2 hours pituitrin in 1 minim dosage is given intramuscularly at from 30 to 60 minute intervals. Usually no more than 2 doses are required.

There was no mortality in these cases and the maternal morbidity was less than the general average for the past 10 years. The gross fetal mortality was less than 2 per cent which is less than the general fetal mortality for the past 10 years. A physician is justified in making labor easier for his patient provided he can accomplish it safely. The results here presented show that the elective induction of labor in properly selected cases or in other words, the precipitation of imminent labor is a justifiable procedure.

JOHN R. WOLFE, M.D.

Induction of Labor at the Chicago Lying In Hospital. WM. J. DIECKMANN and R. EST. B. McCREADY. *Am J Obst.* 1947 54 495.

When the termination of pregnancy is indicated after 32 weeks, the doctor must choose either cesarean section or the induction of labor. The latter would be completed preferably by vaginal delivery and rarely by cesarean section. Induction of labor is indicated in comparatively few cases as compared with 25 or more years ago when the cesarean section mortality was 10 per cent or more.

The primary consideration must always be: Is the patient better off with the uterus empty? or if the infant is alive and in good condition are its chances of survival increased by early delivery? The indications for the induction of labor are selected cases of placenta previa, abruptio placenta, eclampsia and nonconvulsive toxemia of pregnancy. The induction of labor for postmaturity, contracted pelvis or the convenience of either the patient or doctor is contra-indicated. In the hemorrhagic groups the patient should be delivered vaginally if she possibly can be without undue hemorrhage. In the patients with toxemia one must evaluate the condition of the cervix and severity of the toxemia. If the latter permits delay the cervix will change and permit relatively safe induction of labor.

Rupture of the membranes is the simplest and easiest means of inducing labor. Castor oil and quinine have no place in this technique. A vaginal examination with sterile technique should precede all attempts at induction. A careful evaluation of the pelvis, the determination of the presenting part, and the exclusion of a concealed prolapse of the cord, as well as the condition of the cervix must be determined. If the cervix is "ripe" labor can be successfully induced and delivery completed within 24 hours in more than 80 per cent of the patients. The incidence of attempted induction of labor at the Chicago Lying In Hospital, Chicago is 3.3 per cent, with a failure of induction in 9 per cent.

The induction of labor is inevitably followed by an increased maternal and fetal morbidity and mortality irrespective of how carefully the cases are selected.

JOHN R. WOLFE, M.D.

The Management of Prolonged Labor. HERBERT E. SCHWITZ, JAM. A. N. B. EWING, JAMES E. TOWNE, and GROSCE R. HARR. *Am J Obst.* 1947 54 615.

One of the most trying complications of pregnancy confronting the obstetrician is the management of prolonged labor. In this investigation 24 hours has been selected as the limit beyond which the labor is considered prolonged. Labor was considered to be initiated with the onset of regular uterine contractions associated with pain regardless of the presence or absence of effacement, dilatation of the cervical os or rupture of the membranes.

In the 4 year period between July 1, 1942 and June 30, 1946 5,509 patients were delivered at the Lewis Memorial Maternity Hospital, Chicago. Of these, 224 (4.0%) patients had labor exceeding 24 hours duration. The cases excluded obstructed labor due to complicating tumor or disproportion and were confined to those in which normal progress was expected but did not materialize. The authors believe that presentation and position do not materially influence the first stage of labor in the majority of the cases. They do however play a more important part in the second stage and its management hence, the cases of brow, breech and transverse presentations are included.

The routine procedure of management is based on extreme conservative care directed toward anticipating and combating infection and exhaustion during the antepartum phase and maintaining a constant vigil for hemorrhage and shock during the postpartum phase.

As it is an established fact that the incidence of infection is increased as the duration of labor is lengthened particularly after the rupture of the membranes rectal and vaginal examinations are kept to a minimum. Every effort is made to avoid vulval contamination during rectal examination and all vaginal examinations are made in the delivery room under strict aseptic technique.

Dehydration, starvation, and exhaustion are combated by the early institution of a dietary regime which includes small feedings of a soft diet every 4

hours. Liquid intake by mouth is encouraged. In the event that the patient is unable to retain food or liquid by mouth 1,000 c.c. of a 5 per cent glucose in saline solution is administered twice a day or oftener if indicated. Exhaustion is combated by an 8 hour period of rest alternating with a like period of labor. Morphine sulfate was the drug of choice in these cases as the barbiturates not infrequently caused excitation in the patient.

When labor has been in progress for 24 hours the urine is examined every 6 hours for acetone and albumin and the fluid output checked carefully. In the event of the appearance of acetone and diacetic acid in the urine, with a rising pulse rate and signs of impending collapse, the patient is heavily sedated and placed on continuous fluids.

During the period following the sedation the labor usually progresses without stimulation. In a few instances in this series intravenous calcium gluconate, quinine and rarely small doses of pituitrin were used.

Delivery is not attempted in any case until the first stage is terminated and the cervix completely dilated. Major operative procedures are discouraged during the second stage unless the conditions and indications warrant interference.

Following delivery the patient is kept in the delivery room under sterile drapes for a period of an hour. The blood pressure is checked every 15 minutes or oftener if indicated. Early use of plasma and whole blood are encouraged. Intrauterine packs are used to control hemorrhage when needed, but such a procedure tends to increase the danger of infection.

The prolongation of labor is usually due to the prolonged first stage. The duration of the first stage is dependent on two main factors: (1) resistance of the cervix to dilatation and (2) the all important intensity and frequency of the labor pain. Prolonged labor caused by cervical dystocia is usually due to congenital anomaly, severe scarring from previous trauma or long standing infections with resulting fibrosis or scarring. In the authors series, however there was no instance in which cervical incision was considered to be indicated.

A definite increase of fetal mortality in prolonged labor as well as increased maternal morbidity was noted. There were no maternal mortalities. The elderly primipara group showed a higher percentage of prolonged labor than the younger group. It also showed a marked increase in the fetal mortality.

JOHN R. WOLFF, M.D.

Physiologic Changes in the Circulation during and after Obstetric Labor. ELLIS BROWN, JOHN J. SAMSON, EDWIN O. WHEELER, BENJAMIN F. GUNDELKOR, and JOSEPH E. GIANTRACUSA. *Am Heart J.*, 1947, 34, 311.

By means of various determinations of circulatory function the authors seek to ascertain the effects of emptying the uterus, either by labor or cesarean section. That the work of labor is not alone the cause of cardiac stress is evident from the fact that deaths

from congestive failure occur with as great frequency following cesarean section as after vaginal delivery. Because of the possibility that the pregnant uterus may function as an arteriovenous fistula, of significant proportions, acute changes were sought that might indicate occlusion of such a fistula by delivery itself.

Serial observations both intrapartum and postpartum, of changes in heart rate, arterial blood pressure, vital capacity, venous pressure, hematocrit values and plasma volume (using T 1824) were carried out on a total of 24 patients. These included patients both with and without cardiac disease, and patients delivered vaginally and by cesarean section without a trial of labor. Only the results of the last three mentioned studies were sufficiently uniform to lead to definite conclusions.

On the basis of the shunt hypothesis, a rise in venous pressure would be expected postpartum. Contributing causes however may consist of increased blood return from exercise and blood expressed from the uterus by oxytocic drugs. The increase in venous pressure was less marked following vaginal delivery than after cesarean section. It is postulated that during the uterine contractions of labor intermittent increases of venous pressure produce filtration of fluid from the capillaries and therefore a gradual reduction of blood volume. To minimize the effects of increased venous pressure it is recommended that oxytocics be used cautiously in heart disease especially in the presence of congenital intracardiac shunts.

Hematocrit and plasma volume estimations agreed with previous observations that (a) with delivery a significant quantity of fluid leaves the blood stream, (b) a volume equal or greater to this re-enters the vascular compartment on the second day of the puerperium or later, and (c) probably through diuresis the blood volume returns gradually to normal.

The authors conclude that though not conclusive, their findings at least suggest that delivery of the fetus either by vaginal or cesarean delivery produces effects resembling those following obliteration of a large arteriovenous shunt.

WARREN R. LANG, M.D.

Shock in Obstetrics. W. A. SCOTT. *Brit M J*, 1947, 2, 647.

The author states that the mechanism of surgical shock is as yet unknown, but clinically he has observed a group of cases characterized by hypotension, decreased blood volume, decreased cardiac output, and hemoconcentration which present a common clinical picture regardless of etiology. It is emphasized that these patients present a group of symptoms and not a disease, and that prevention and treatment are of primary importance.

The author states that in the urban centers there has been a great reduction in the number of maternal deaths due to shock in the past 25 years. The great majority of cases of obstetric shock can be attributed to hemorrhage. This was shown quite conclusively by

an analysis of the maternal deaths in the Province of Ontario, Canada, for 1943.

A review of 12,749 deliveries at Toronto General Hospital, Toronto, revealed 109 cases of postpartum hemorrhage with 6 deaths. The mortalities occurred in the patients with a blood loss of 1,000 c.c. or over and death ensued within a period of 63½ hours from the time of birth. It is stated that most of these fatalities were due to errors in judgment.

The predisposing factors to the development of obstetrical shock are excessive blood loss, labile vasomotor system, increased capillary permeability and trauma. This is manifested clinically in the following obstetrical emergencies: postpartum hemorrhage, rupture of the uterus and eclamptic toxemia.

The author states that the treatment of obstetrical shock is prophylaxis. Any pre-existing predisposing factors should be corrected upon recognition.

The active treatment of shock consists of immediate and complete relief of pain, maintenance of body heat and the replacement of circulating blood volume by whole blood if possible, otherwise the use of plasma or glucose solution is indicated; the bleeding should be controlled at its source. If surgery is indicated, it should be performed only after the shock has been corrected. J. ROSE & WILLIAM M.D.

PUERPERIUM AND ITS COMPLICATIONS

The Placental Stage and Postpartum Hemorrhage. Wm. J. DIECKMANN, LECTURER D. O. BELL, VICTOR M. WILLIAMS, A. THOMAS G. SEVER, and RUSSELL PORTINGER. *Am J Obst* 1947 54: 43.

Even in this age of atomic energy, women still die of hemorrhage associated with parturition. Hemorrhage caused 50 per cent of the maternal deaths which occurred in the United States in 1944 and 1945. These deaths were either preventable or they occurred as the result of preventable factors. A marked reduction in the incidence of postpartum hemorrhage due to uterine atony will follow the proper conduct of the late second and early third stages of labor. The importance of a definite routine for the prevention and treatment of postpartum hemorrhage is stressed.

The prevention of postpartum hemorrhage is much easier than its treatment. Prevention begins with the proper conduct of the terminal phase of the second stage of labor. For a proper separation of placenta, it is of utmost importance that the baby be delivered slowly—in stages with a 30 to 60 seconds pause after the delivery of each shoulder—which requires a total of at least 3 minutes. Thus, the uterine wall is given time to contract and retract thereby tearing itself away from the placenta; the latter has usually separated within less than 1 minute. After the fetus has been expelled, as soon as the uterus retains its globular form it should be compressed but not pushed into the pelvis. When the placenta is in the vagina it should be extracted by pulling on the cord. Although an oxytocic is not necessary for the

separation of the placenta under normal conditions, with patients under analgesia and anesthesia, one unit of a solution of posterior pituitary or 0.2 to 0.4 mgm. ergotrate should be injected intravenously after delivery of the posterior shoulder, if the doctor is experienced. If he is not, then after the delivery of the placenta. This will prevent excessive bleeding after the placenta.

If the placenta cannot be delivered and there is no bleeding, one may wait a maximum of 1 hour but all retained placenta should be manually removed at the end of this time.

Uterine hemorrhage is treated by the immediate removal of the placenta manually if necessary or after the third stage by manual palpation of the uterine cavity and visual inspection of the vagina and cervix. One of the oxytocics mentioned above should be injected intravenously and repeated one time. If the bleeding continues, the uterus must be packed. A transfusion of 1,000 c.c. or more of blood, if necessary, must be given at once. Periodic hemoglobin or hematocrit determinations must be made. J. ROSE & WILLIAM M.D.

NEWBORN

New Methods in the Treatment of Asphyxia of the Newborn (Neue Methoden in der Behandlung asphyktischer Neugeborenen). R. BICKENBACH. *Arch med Klin* 1947 71: 434.

In order to overcome the anoxia of the respiratory center it is important to supply the newborn with as much oxygenated blood as possible. The placenta represents a reservoir of oxygenated blood and it has been shown that under normal conditions, 51 per cent of the blood in the placenta flows through the cord within the first minute after birth. This amount and the rate of flow can be increased to 76 per cent and 30 seconds, respectively, by utilization of the force of gravity and by manual expression of the cord.

Immediately after birth the newborn is grasped by the feet and is held head downward, as far below the level of the placenta as the length of the cord will permit. By this method of antegrade transfusion the blood volume of the newborn is increased by about 75 c.c., i.e., approximately one fourth of the total blood volume. In the majority of cases this technique alone is sufficient to start the respiration. The author was able to show that the hydrostatic pressure in the umbilical cord is increased considerably by this procedure.

In addition to this mechanical method, coramine or other analeptics may be injected into the umbilical vein about 10 cm. distal from the umbilicus. This should be done within 30 seconds after delivery because the circulation stops in most cases about 1 minute after birth.

The usual methods of artificial respiration are often unsatisfactory in asphyxia of the newborn because the lungs are atelectatic and the thorax is in the position of extreme expiration. Better results are

achieved by using the resuscitator which permits expansion of the lungs under positive pressure. To stimulate the respiratory center, from 3 to 6 per cent of carbon dioxide should be added to the oxygen.

WERNER M. SOLMITZ, M.D.

MISCELLANEOUS

Relationship between Erythrocyte Sedimentation Rate, Sludged Blood, and Plasma Proteins during Pregnancy LESTER D. ONELL, GLORIA T. ARAGON, and RUSSELL E. POTTINGER. *Am. J. Obst.* 1947 54: 596

The purposes of this article are (1) to report the presence of "sludged blood" in women during both normal uncomplicated pregnancy and during pathologic pregnancies (2) to report that the masses of agglutinated red cells are larger in certain of the pathologic conditions examined than in the uncomplicated pregnancies (3) to point out probable relationships between (a) the intravascular agglutinations of the blood, (b) the increased in vitro sedimentation rates of blood from these patients and (c) changes in the concentrations of certain plasma protein fractions.

It is stressed that rouleaux formation differs, by definition from an intravascular agglutination of cells (or sludge). The former consists of an in vitro piling up of red cells like coins, one on another; the latter of in vivo intravascular cell aggregates where-in erythrocytes are held together at all angles to each other. The authors suggest that both phenomena relate to an increased cellular cohesiveness and the nature of the substance causing this should become an object for much research.

A total of 52 pregnant and nonpregnant subjects were selected for study. These included 31 whose pregnancy was normal and 23 whose pregnancy was complicated: 16 with toxemia, 4 with thrombophlebitis and infection, 2 with acute hemorrhagic shock and 1 with ectopic pregnancy. Nonpregnant controls numbered 8.

The lateral bulbar conjunctiva was viewed with a Zeiss dissecting microscope. The size of intravascular masses and the degree in reduction of rate of flow were evaluated in fine, medium and large venules and in arterioles. Sedimentation rates were estimated on the basis of these direct microscopic observations and were measured in vitro. Fibrinogen and total serum proteins were determined on the interferometer. Albumin and globulin fractionation was obtained.

Observations by microscopy numbered 103. 77 of these are tabulated with simultaneously obtained sedimentation rates and plasma protein values.

Nonpregnant controls. In none of 6 female subjects studied whose sedimentation rates were below 24 mm./hr. was any intravascular agglutination of the blood observed. In 2 patients, whose diagnoses were pelvic inflammatory disease and generalized carcinomatosis there were large easily observable agglutinations within the venules and arterioles. a

reduced rate of blood flow and in some vessels a temporary cessation of the flow as anticipated the sedimentation rates were high.

Normal pregnancy. Sludged blood, consisting of intravascular agglutinations of erythrocytes and reduced rates of flow with temporary cessation of flow in some vessels, was observed in all subjects with sedimentation rates of 33 mm./hr. or more. The largest cell masses and the greatest reduction in flow were seen in the patients who were near term in labor or early in the puerperium.

Pathologic pregnancy. In toxemia of pregnancy a noticeable narrowing of the arterioles could be detected in most of the patients. These vessels were not affected in normal pregnancy. In addition, intravascular agglutinations and reduced flow rates were observed. The sizes of masses comprising the sludge were larger the rate of flow was considerably more decreased and cessation of the flow was more prolonged as compared with normal pregnancy.

Thrombophlebitis and infection. Identical evidences of sludged blood were seen. The sedimentation rates were unusually high in these patients.

Hemorrhagic shock. Three instances of severe hemorrhagic shock were observed in the same patient. Evidence of sludged blood appeared and was relieved by blood replacement therapy. Intravascular agglutinations were again noted after operative procedures with their attendant trauma. Thus appearance of sludged blood in the experimental animal has been noted.

Sedimentation rate. Conjunctival observations closely approximated the measured, uncorrected hourly values. Values were higher at term in labor or during the puerperium and highest in infections. In addition the sedimentation rates of patients with pregnancy toxemia tended to be higher than those of women with normal pregnancy. There was close correlation with plasma fibrinogen values, less with albumin, globulin, or the albumin-globulin ratio and no relationship with total serum proteins.

Fetal and Maternal Mortality N. S. ASHALL and L. F. ZACHARIAS. *Am. J. Obst.* 1947 54: 651

This article represents a compilation of the data collected in a survey covering an 11 year period from January 1935 through December 1945, at the Department of Obstetrics, Bethesda Hospital, Cincinnati, Ohio. The 11 years are considered in two periods, the first from 1935 to 1940 and the second from 1940 to 1945.

Deliveries by general practitioners predominated in the first period. This period was also characterized by abuse of cesarean section, the use of high forceps and lack of control of the obstetric procedures. In consequence, a high fetal and maternal death rate was noted.

Although obstetricians continued to deliver a relatively small proportion of the patients at the outset of the second period significant modifications in pol-

icy occurred. Rigid rules were established by the Obstetrical Committee regarding the performance of cesarean section and the use of the high forceps. Frequent utilization of obstetric consultants was required and supervision of the delivery was instituted. These changes brought about definite improvement in standards of practice with consequent decrease in maternal and fetal mortality. The improvement has been increasingly evident in the latter years of this period.

In the hands of the obstetric staff breech delivery has received particular attention in recent years. Increasing emphasis on external version and careful roentgenologic study in cases of breech presentation have made possible accurate determination of cephalopelvic disproportion with consequent reduction in the number of unnecessary cesarean sections. In addition the use of the bag for dilatation of the cervix and routine episiotomy have made breech delivery less traumatizing.

Despite the continued efforts of obstetricians and pediatricians little has as yet been accomplished in the reduction of mortality attributable to prematurity. It is the authors' hope that by the more extensive employment of the procedures and principles noted concerning breech delivery plus more circum-

spect use of maternal sedation, constant use of pediatric consultation and improved management of toxemia the mortality among premature infants will be reduced.

Fifteen thousand and eighty-eight deliveries occurred during the 11 years of this report. For the entire period the gross fetal mortality was 4.5 per cent, and the corrected mortality 3.5 per cent. Although the results have been improved in the more recent years these figures still remain high.

Breech and version delivery resulted in the highest and low forceps delivery in the lowest fetal mortality rate.

The fetal and maternal mortality among deliveries by general practitioners was higher than that of obstetricians.

Prematurity was the major fetal contributing factor and toxemia the major maternal factor causing fetal death.

The gross maternal mortality was 0.18 per cent and the corrected 0.17 per cent. It has steadily decreased throughout the past few years during which time it has ranged between 0.10 and 0.13 per cent.

Hemorrhage and shock, infection, toxemia, and heart disease were the major causes of maternal death.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

The Suprarenal Cortical Syndrome WILLIAM L. MCLACHLIN, JON P. BOWLER and JARRETT H. FOLLEY, J. C. Balt. 1917 58 221

The suprarenal cortical syndrome is defined as the sum of metabolic changes produced in the body by the presence of an excessive amount of a renal cortical steroids. This excess of steroids may be the result of hyperplasia of the adrenal cortex brought about by the adrenotropic hormone of the pituitary gland or a primary tumor of the adrenal cortex.

The authors presented a patient with a clinical picture of suprarenal cortical syndrome that was produced by carcinoma of the right adrenal gland. Following the extirpation of this neoplasm the patient developed a state of adrenal insufficiency which resulted in a slow but complete recovery. Without identifying the type or types of excess steroid the authors stated that their patient's adrenal cortical neoplasm produced steroids of considerable biologic activity. ROBERT THRELL, M.D.

Ureteral Transplantation and Cystectomy VICTOR F. MAXWELL, J. Urol., Balt. 1947 58 244

Transplantation of the ureters and total cystectomy is a surgical procedure of considerable magnitude which carries a postoperative mortality of at least from 10 to 20 per cent. Radiation therapy for bladder cancer carries a much lower immediate mortality so that before advising the surgical program the surgeon should have some definite reasons in mind.

First of all, how effective is radiation in the treatment of bladder cancer? Three hundred consecutive bladder cancer records at the Memorial and New York Hospitals from 1932 to 1938 inclusive were reviewed in detail. Papilloma was excluded and it must be stressed that the pathologists' criteria were very strict excluding from the cancer classically even atypical papillomas which are commonly considered of low grade malignancy. Only 53 patients or 1 per cent were known to have survived 5 years and only 27 (50%) of these could be called 17 patients representing 5 year successful results. These will not all stand as cured upon critical review as at least 5 created some doubt in regard to the diagnosis of cancer at least 5 were in poor condition at the 5 year anniversary and at least 5 died subsequently without a reliable record of the cause of death being obtained. Furthermore 3 were clinically free of disease because cystectomy had been deferred after the failure of radiation therapy. All points considered, it would be reasonable to say that by the author's radiation method 14 of the 1010 at the 5 year successful result rate was approximately 6 per cent. The average survival was 34.5 months for a group of 316 patients who were treated with a 5 year follow-up.

This hardly compares favorably with results of non-treatment as reported elsewhere in which the average survival was 18.8 months and approximately 20 per cent of the patients survived 5 years.

The simplest surgical treatment of bladder tumors is local destruction by fulguration. On review of the author's old and recent records very few good results were obtained by this method and the overwhelming majority of tumors proved to be no more than papillomas histologically and not cancer especially when the result was not obviously a failure. Most of the few good results were obtained when small well localized and low grade lesions were present but there were so many apparently similar cases which resulted disastrously that the criterion for choosing candidates was not evident. Few interstitial cancers are cured by simple local destruction and a complete follow-up on histologically proved bladder cancer indicates no major exception in the author's experience.

Thirty three bladder resections done within the past 5 years have resulted already in 11 known recurrences in the bladder and 3 postoperative deaths. Twelve of the 33 patients are now known to be dead. Even so the average survival was 20 months in spite of the fact that the follow-up was 2 years in 17. Several patients have had excellent results thus far but the impression is unavoidable that in the anxiety to preserve bladder function and avoid more immediately hazardous surgical procedures resection was done on lesions which were too large on lesions in which the margin of removal was multiply within the bladder.

Total excision of the bladder is usually not a difficult or dangerous operation in itself as was shown by the occurrence of only 2 deaths in more than 100 cases a mortality of 2 per cent or 1. However the real surgical problem is the safe and permanent diversion of the urinary stream prerequisite to cystectomy. Transplantation of the ureters to the skin is a relatively simple procedure and in the author's experience almost all postoperative deaths could be obviously attributed to the poor preoperative condition. Structure and access formation is associated with incontinence if my catheters become more common the larger the follow-up is continued. Occasionally calculi have seemed better than catheters with uterine catheters complications but only a few patients can manage them. At least the patient can wear a cumbersome but functional apparatus at least it is unobjectionable. If the ureters are transplanted to the bowel above a normal anal sphincter the patient does not need an apparatus which is socially acceptable.

and, except for the necessity of sitting to urinate which half the population does naturally appears outwardly normal. However the problem is not simple because the immediate and late risks of ureterointestinal anastomosis are not only greater but are usually of more grave importance after skin transplantation.

The author transplanted the ureters to the bowel in 304 patients by the Colley I intraperitoneal method. Thirteen deaths resulted a mortality of 12.5 per cent. Two patients died of peritonitis from leakage and 1 from small intestinal obstruction at the operative site. This 2.8 per cent represents the only postoperative mortality due to complications in the peritoneum the urinary tract or the gastrointestinal tract. Of the remaining 10 deaths, 3 were due to congestive cardiac failure 3 to embolism 3 to carcinomatosis, and 1 to the effects of a radical operation on a recurrent urethral carcinoma. The author emphasizes the fact that this series includes palliative cases and that only 8 patients had transplantation for conditions other than neoplasm. The oldest patient was 83 and 7 were in the 70's. Thirty three, including the 13 just mentioned are known now to be dead and 71 are living from 1 to 36 months. Temporary nephrostomy was necessary on 3 patients and 1 other patient is now carrying nephrostomy tubes during convalescence from cystectomy. One nephrectomy was necessary. One ureter was successfully implanted into the bowel a second time. Three patients had one or both ureters transferred from the bowel to the skin because of poorly functioning ureterointestinal anastomoses. In brief of the 307 urethral transplantations to the bowel 26 were unsuccessful because of the postoperative death of the patient 1 was unsuccessful as nephrectomy became necessary 5 were failures because the ureter was necessarily transferred to the skin and 3 at this time must be called failures because the patient is wearing bilateral nephrostomy tubes. The second implantation of one ureter was only a partial failure as the second attempt remained successful over a year later. Thus, of 307 transplantations 34 were immediate failures but 173 or 56 per cent were early successes.

JOHN A. LOER M.D.

BLADDER, URETHRA, AND PENIS

An Artificial Sphincter. FREDERIC E. B. FOLEY J
Urol. Balt. 1947 53 350.

In true incontinence there is escape of urine through an anatomically or neurologically incompetent sphincter. With complete incontinence the bladder is always empty. With incomplete incontinence the bladder partially fills and the urine which is excreted into the bladder in excess of "continent capacity" is not retained but escapes through the urethra.

Anatomic incompetence of the urethral sphincter is usually the result of trauma, obstetric, surgical or otherwise. Neurogenic incompetence of the sphincter is due to organic disease of the central ner-

vous system injury or anomaly causing permanent relaxation of the external sphincter. In females, incontinence may be caused by "idiopathic" relaxation of the sphincter which is not of traumatic or neurogenic origin.

Control of incontinence in the new way presented by the author is accomplished by a very simple mechanical device which functions pneumatically. The device has been called "an artificial sphincter." It is applied to the urethra which is compressed by air to prevent the escape of urine.

The artificial sphincter may be applied to the urethra in its normal anatomic relationships or to a segment of urethra surgically isolated from adjacent structures by a new operation which has been called a cutaneous tunnel operation.

The artificial sphincter consists of a pneumatic or inflatable incontinence clamp which compresses and occludes the urethra and an inflating device communicating with it by means of an air passage of rubber tubing. The device is carried in the pocket of the trousers.

The purpose of the cutaneous tunnel operation is to permit application of the pneumatic incontinence clamp to an isolated segment of urethra without encirclement and constriction of the rest of the corpus, particularly the cavernous bodies, to the end of avoiding engorgement and partial erection distal to the site of application. This form of application permits maximal effectiveness in occluding the urethra by a clamp of minimal size requiring the smallest possible displacement of air. JOHN A. LOER M.D.

Exudative Cystitis. J. A. BERRY and E. BERRY J
Urol. Balt. 1947 53 360.

In a series of 24 cases of acute exudative cystitis, a few cases were complicated by arthritis, conjunctivitis, iritis, and dermatitis.

The acute vesical syndrome is characterized by a profuse bacterial pyuria and gross hematuria. The end result of the inflammatory lesion is a contracted and ulcerated bladder with terminal ureteritis and marked dilatation of the upper urinary tract.

The authors believe that the condition is caused by an organism possibly a spirochete and that it has some relation to nonspecific urethritis.

The differential diagnosis concerns the exclusion of gonorrhea, tuberculosis and malignancy. Familiarity with the symptoms and the roentgenographic findings makes the diagnosis simple.

Characteristically the whole picture can be reversed in a short period of time with specific treatment usually the neosarphenamines are employed. Mapharsen in the experience of the authors, has been equally efficacious. JOHN A. LOER M.D.

The Treatment of Serious Tumors of the Bladder. R. OCHER WARD, ARTHUR JACOBS, II, F. WIDEBURY WHITE, DAVID BAND, and Others. *Brit. J. Urol.* 1947 9 744.

In this symposium it was attempted to assess the relative values of partial and total cystectomy

WARD classified bladder growths as papillomas, both 'potentially' benign and 'potentially' malignant and carcinoma divided into infiltrating and noninfiltrating papillomatous types nodular and ulcerative types and adenocarcinomas. In potentially malignant papillomas he gives cystoscopic fulguration (diathermy) a trial first. In true carcinoma, when partial cystectomy is employed he removes the entire growth together with a wide margin of mucosa and the entire thickness of the bladder wall. Reimplantation of the ureter into the bladder is done whenever necessary. The worst results occurred in nodular infiltrating carcinoma. Possibly the growth was not removed widely enough (with sufficient margin of apparently healthy tissue). Excision should be done with a diathermy knife. Another cause of failure is the failure of recognition of extensions outside of the bladder in the adjacent tissue. In open operations upon papillomas reimplantation of pieces of tumor may occur. Iliae lymph nodes may already be involved at the time of operation. Distant metastases may be present. Ward palpates the liver through the opened peritoneum in each case. He thinks that total cystectomy is most effective in cases of malignant papilloma and much less effective in nodular or ulcerative growths. If a wide excision is impossible in attempting partial cystectomy the operator must go further and perform total cystectomy whatever its disadvantages and imperfections. Deep x ray therapy after radical operation is useless.

Preoperative accurate diagnosis should include accurate estimation of the size and appearance of the growths cystoscopically, possibly by insertion of a graduated ureteral catheter alongside the tumor. The posterior urethra should be inspected. A cystogram outlines large growths well. Excretory urography demonstrates ureteral obstruction and possible renal tumor. Bimanual examination under anesthesia is very important. A search for distant metastases is necessary. Cystoscopic biopsy should be done whenever reasonable. At operation the liver should be palpated, the extravascular extent of the growth estimated and the regional lymph node area should be examined. Ward suggests that when the partial cystectomy is completed a further small piece of adjacent mucosa and muscle in apparently healthy areas should be removed for examination. A pathologist should be present at the operation.

JACOBS employs segmental bladder resection only when the size and situation of the growth permits concomitant excision of a wide margin of healthy tissue as in tumors in the middle and upper zones of the lateral and posterior walls and on the superior wall. Tumors of the base or lower lateral walls are treated by open operation and insertion of radium. Good long term results are expected only when the tumors are of the papillary type. In advanced infiltrative growths total cystectomy is not worth while.

WENKSBURY WHITE employs interstitial implantation of radium needles. He found considerable lack of vesical irritation in cases of long survival.

BAND believed that total cystectomy was the operation to be aimed at. An infiltrated organ should be extirpated and if the tumor is not removed toxic absorption makes the patient gravely ill.

GALBRAITH believes that a cure is not a matter of 5 years but of from 15 to 30 years. Frequent follow up cystoscopy has been employed in his clinic for several years, with annual cystoscopy for at least 5 years thereafter. Small growths are fulgurated in the outpatient department without anesthesia. Low spinal anesthesia is used in large tumors and difficult cases. A patient unsuitable for transurethral treatment is hospitalized and treated by open bladder fulguration. Partial cystectomy is employed for ulcerated or infiltrating tumors. Radium needles are employed in selected cases. All radiation therapy is guided by a radiologist.

BERNARD WARD performs extensive fulguration on papillary growths. He prefers early cystectomy on primary ulcerating malignant growths. When infiltration of the base is rectally palpable the growth is inoperable.

TAIT (Australia) urged the active co-operation of the radiologist when radium is employed. Partial cystectomy is employed when the growth is not large.

MACK uses radium frequently even when a papilloma is fulgurated and the bladder wall at the pedicle base seems normal. Infiltrating tumors are thoroughly removed with the diathermy loop, the base is fulgurated and 0.5 or 1.0 mgm. radium needles are inserted at the tumor periphery. They are subsequently removed (usually in 7 days) through the suprapubic wound by withdrawing them with the attached linen threads. The suprapubic catheter remains in place for 3 weeks.

Total cystectomy is decided upon only after inspection of the growth in the opened bladder. If total removal is indicated the bladder is closed around a suprapubic tube, one ureter is transplanted and the bladder is removed when the other ureter is transplanted in a few weeks.

ROCHZ stated that loin pain associated with bladder tumor suggests ureteral obstruction usually by carcinoma rather than papilloma. In performing partial cystectomy he has ligated the ureter rather than reimplanted it.

WADZ used free wide excision, without fear when performing partial cystectomy.

POOLE WILSON suggested the use of radioactive fluid to prevent recurrences of bladder tumor in dye workers.

In summing up, the discussion disclosed differences of opinion about (1) the desirability of general anesthesia for cystoscopic fulguration (2) the wisdom of opening the bladder before deciding on treatment (danger of dissemination) and (3) the relative value of surgery and irradiation. There was general agreement about (1) the need for early cystoscopy and repeated follow up (2) the difficulty of deciding whether a growth was benign or malignant, (3) the necessity for combined treatment and (4) the belief that total cystectomy had its greatest field of use

fulness in the more extensive but less malignant papillary tumors. DAVIN ROSENTHAL 31 D

Transurethral Resection in the Treatment of Vesical Dysfunction Secondary to Inflammatory Degenerative and Traumatic Lesions of the Spinal Cord JOHN L. EWERTT and J. L. DIS-
QUIRRE Surg. Clin. N. Amer. 1947 32 950.

Prather suggested that the proper treatment of the acute phase of vesical dysfunction resulting from lesions of the spinal cord should consist of continuous drainage provided either by an indwelling urethral catheter or a suprapubic cystostomy tube. When these methods are used the bladder is kept clean by means of a closed system of irrigation by either the intermittent or automatic (tidal) method. The choice of urethral or suprapubic drainage depends on various factors among which are (1) the facilities available for the care of the patient (2) the type of nursing service, (3) urethral tolerance and (4) the length of time drainage is expected to be necessary. Some patients are able to tolerate an 18 F bag urethral catheter for long periods with no untoward results. In other cases there is a tendency for urethral infection and prostaticitis to develop; these complications may result in prostatic abscess (usually at the penoscrotal junction) and fistula. It is important to avoid such complications if possible as they greatly complicate treatment in the chronic stage. Administration of small doses of one of the sulfonamide drugs while a urethral catheter is in place will assist in the prevention of such complications. Each case must be considered individually; however, final decision is a matter of keen judgment on the part of the physician.

The matter of the closed system of irrigation is important. Munro and Hahn have advocated the automatic (tidal) variety of irrigation. They and other authors have demonstrated that the urine may be kept free of infection for long periods of time with this type of treatment; however, their assertion that tidal drainage will prevent hypertonicity and spasticity of the bladder in the chronic stage has not been substantiated by other authors.

The therapy of the chronic stage of the neurogenic bladder is primarily a problem involving the treatment of various types of hypertonic cord bladder. Almost the only exception to this statement is the atonic tabetic bladder. Vesical dysfunction in the tabetic patient responds well to transurethral resection of the vesical neck.

The remaining consideration therefore will concern the various types of hypertonic neurogenic bladders which constitute the overwhelming majority that are the end result of lesions of the spinal cord.

A total of 65 patients with chronic cord bladder have undergone transurethral resection at the Mayo Clinic prior to January 1946. Forty-five of these patients had transverse lesions of the spinal cord, while the remaining 20 had other lesions of the spinal cord, such as multiple sclerosis, combined sclerosis and miscellaneous lesions.

All of the transurethral resections in this series of cases were done with the Thompson cold punch with the usual technique. The object of the operation is to remove the vesical neck (so-called internal urethral sphincter) and any prostatic enlargement that is present. The resection must be complete and should be carried out to the region of the external urethral sphincter. If the external sphincter is not damaged incontinence will not result. The resection must frequently be done in multiple stages. Although the surgeon may feel sure that the resection has been complete, he will often find on subsequent examination that as much or more tissue can again be removed. It is wise to perform the resection in multiple stages in some instances because if one tries to resect too deeply in the muscular tissue at the vesical neck at the first stage, troublesome bleeding may be encountered and may prove difficult to control. In the 45 cases of transverse lesions the resection was done in one sitting in 34 cases, in two stages in 7 cases, in three stages in 3 cases and in four stages in 1 case. The amount of tissue removed is usually rather small unless the patient is an elderly person. However, young patients in whom the cord lesion has been present for many years may have a large amount of hyperplastic tissue at the vesical neck. In the series of 45 cases under consideration, the amount of tissue removed varied from 1 to 34 gm.

The results of transurethral resection in these 45 cases were gratifying. Excellent results were obtained in 33 cases, in 7 cases, the patients were greatly improved, in 3 cases fair results were obtained and in 4 cases the patients were unimproved.

Surgical treatment should be postponed until the patient is in good general condition and until the decubitus ulcers are well controlled. It would also be desirable to await some return of vesical tone. Whether or not one should wait longer than 3 or 4 months for this to occur is doubtful, however.

The results of transurethral resection in cases of multiple sclerosis have not been as consistently good as the results in cases of transverse lesions of the spinal cord. Three patients obtained good results, and in the other 4 cases the results were only fair. Resection was done only once in each of the 4 cases in which the results were fair; therefore it is entirely possible that further resection might have been beneficial, as is so often true in cases of transverse lesions.

Transurethral resection was performed in 5 cases of combined sclerosis and the results were good in 4 cases. Of the remaining 3 cases, the results of transurethral resection were good in 3 and poor in 1 case.

Primary Carcinoma of the Male Urethra. JERRY ZARLOW and JAMES T. PRINGLEY J. Urol., Balt. 1947 58 707

Twenty-five cases of primary urethral neoplasm have been encountered at the Mayo Clinic from 1910 to 1945, inclusive. The diagnosis was established by microscopic examination in all but 3 of these cases. In all of the cases studied histologically the diagnosis was epithelioma. No adenocarcinomas of the glands

of Littre were encountered. Cases of adenocarcinoma in the posterior urethra have not been included.

The growth was situated anteriorly in 10 cases and posteriorly in 14, and in 1 case both the anterior and posterior urethra was involved a proportion in accord with reports in the literature. There was little difference in the symptoms and clinical characteristics regardless of the location of the growth, however the most common initial symptom for an anterior lesion was difficulty in micturition whereas for a posterior lesion hematuria was most often the presenting symptom. If a growth is of appreciable size it can be palpated especially if it is located in the anterior urethra. Six of the 25 patients presented a history of urethral stricture prior to the onset of symptoms referable to the neoplasm an incidence which seems somewhat more than coincidental. The average age of the patients was 56 years and the youngest one was only 28 years of age. The grade of malignancy was determined in 20 cases and in 19 was either 2 or 3.

Treatment varied according to the location and extent of the lesion. In the 10 cases in which the growth was located in the penile urethra amputation, radium, and fulguration were employed with equal frequency. Amputation which may be partial rather than complete, is preferable for the more extensive lesions. It is well to remember however that a partial amputation which leaves virtually no urethra which may be grasped during micturition to direct the stream may be more of a handicap to the patient than a perineal urethral meatus which can always be used satisfactorily in the sitting position. For a relatively small growth in the region of the fossa navicularis radium may be applied directly. Fulguration can be used to destroy a relatively small lesion. If there is any doubt regarding the complete destruction of the growth *in situ* by either of these methods, amputation would seem the treatment of choice.

Treatment of an epithelioma situated in the membranous or prostatic urethra is somewhat more difficult. In the present series of cases, prostatectomy, cauterization, application of radium, transurethral removal and fulguration and roentgen therapy were employed. Obviously there must be individualization in the choice of treatment, according to the exact location and extent of the lesion. Experience has been too limited to permit general conclusions but obviously the same principles apply in the treatment of a malignant lesion in the posterior urethra as in other parts of the body, namely complete removal or destruction of the growth if at all possible.

The prognosis in the anterior cases seems more favorable for lesions in the anterior than in the posterior urethra. Since at least half the patients with anterior urethral lesions are living 5 years after operation, while half of those with posterior urethral lesions were dead a year after operation probably the difficulty of complete removal of a growth situated posteriorly may be a factor in this regard. Of

the 10 patients who had an epithelioma in the anterior urethra 3 are known to be dead and 7 are living. Three of these 7 have had a recurrence and none of them is known to have survived for as long as 5 years. The shortest postoperative follow up in this group of 7 patients was 5 months and the longest 5 years, the average being 21 months.

Of the 14 patients who had lesions in the posterior urethra, 12 are known to be dead however 1 of these lived 4 years and another 9 years and at the time of death had no evidence of recurrence. One of the 14 patients was alive and apparently well at least 5 years after treatment and 1 patient has not been traced. The patient who had a lesion which involved both the anterior and posterior portions of the urethra died 4 months after treatment, which consisted solely of roentgen therapy. Obviously the results in both groups of cases leave much to be desired. However the fact that a few patients have survived as long as 5 years affords some encouragement. For the most part treatment in these cases consisted in complete surgical removal or local destruction of the lesion.

GENITAL ORGANS

The Obstructive Prostate. FRANK HUNNAN, J. AM. M. 43: 1247 135 136

The obstructive prostate is of several varieties benign enlargements and median bar formations are almost always obstructive inflammations, cysts, prostatic calculi, leiomyomas and fibromyomas occasionally are obstructive, but cancer is infrequently obstructive unless it is associated with one of the preceding conditions. The present discussion is limited to benign enlargement and carcinoma of the prostate.

The majority of authorities believe that benign enlargement of the prostate is a new growth of fibrous muscular and glandular tissues serving no physiological purpose. It is not invasive but always encapsulated and with growth it compresses the uninvolved parenchyma of the prostate into the so-called false capsule from which it can be enucleated en masse. A theory of origin of the growth assumes that the initial lesion is a fibrous nodule which stimulates extremely early and rapid penetration of glandular elements from the periphery. The process begins in the submucosa of the prostatic urethra and vesicle neck as multiple outshoots of young spindle cells which soon develop into small fibromas and fibromyomas which are quickly invaded by the ingrowth of the adjacent glandular tissues to form the pathological picture of fibromyoadenomas the benign enlargements of the prostate.

Cancer of the prostate also occurs in later life and the two often occur together but are unrelated otherwise. Cancer arises from any part of the parenchyma of the true prostate usually in the periphery. Only early lesions near the surface of the posterior portion are palpable per rectum. All other lesions, no matter where they start would extend to involve

the posterior portion and be palpable but their diagnosis then is late and the late lesion is incurable. Because of the recent advent of endocrine therapy and relief of obstruction in the treatment of cancer of the prostate, the author wishes to determine whether early diagnosis and radical surgical procedures are still applicable in its treatment. In order to better analyze the problem he approaches it from four standpoints: (1) a discussion on what is known about cancer, (2) what happens without any treatment, or with the ineffective methods of radium and x ray therapy, (3) how effective is endocrine therapy, (4) what has been accomplished by early diagnosis and radical surgical intervention?

1. With the lengthening of life expectancy there has been an increase in the number of deaths from cancer. About seventeen million of the approximately seventy million males in the United States are over 50 years of age. The incidence of cancer of the prostate in this group is variously estimated from 14 to 16 per cent. This means that at least three million to five million and possibly as many as eight million Americans now have cancer of the prostate. It is almost universally agreed that primary cancer arises in the prostate gland unrelated to enlargement which arises from the perurethral glands. It seems reasonable to conclude that cancer may start in any portion of this part of the gland. It then spreads within its capsule so that no matter where it started the posterior portion is involved before invasion of the seminal vesicles; hence the problem of early diagnosis is not only the discovery of the primary lesion by rectal palpation but also the development of methods by which the occult forms of cancer which are not palpable may be discovered. According to Kahler involvement of the perineural lymphatics is one of the earliest changes in cancer of the prostate. Opponents of radical intervention believe that lymphatic invasion means metastasis and therefore, since neither the primary or secondary lymph zones of the prostate can be removed, an operative procedure is useless even in early diagnosis. They overlook the fact, however, that this early invasion of lymph spaces surrounding the nerve is confined within the true capsule of the prostate for a long time. Extension into the vesicles, invasion of distant lymphatics, bones, and viscera by way of the blood stream are late manifestations. Complete removal and cure of the lesion while it is limited within the prostate is possible, and has been accomplished repeatedly even when perineural lymphatics in the capsule have been invaded.

2. Studies of what happens without treatment are few but studies which have been carried out indicate that between 90 and 95 of every 100 men will succumb within 5 years of the time cancer strikes them. Inasmuch as the life expectancy at 60 years of age is 17 years, then of 100 men at 60 years, between 80 and 85 of them will be living 5 years later but if all at the age of 60 had had prostatic cancer more than that many would be dead. In other words from 10 to 15 of 100 men with cancer at the age of 60 will die

from other causes and from 80 to 85 will die from cancer within 5 years. This big difference in mortality rates between a group without cancer and a group with cancer shows the error in the general attitude of indifference which arises from a belief that these men haven't long to live anyway.

3. None of the experiences with castration and endocrine therapy have as yet covered a 5 year period. Analysis of the reports which have been presented indicate that in a 5 year period almost as many will die as in the untreated series. The real benefit that most patients with advanced cancer of the prostate derive from hormonal therapy must be minimized. The relief from pain, the improvement of urination with recession of the local growth, and gain in general health are often remarkable. The immediate benefits are not permanent and the cancer may show an increase of virulence later.

4. Of 100 men with cancer of the prostate, only about 5 are seen early enough to justify radical surgical procedures. Series of cases have been reported with 48 per cent and 56 per cent 5 year cure, respectively. Cancer involves the prostatic gland first, arising as a rule near the periphery of that portion involved. It grows slowly in the beginning and there is ample time for early recognition. If it is located in the posterior portion it may be palpable per rectum. If in the lateral, anterolateral, or median portion, it may be suspected and discovered by other methods.

The early lesion in the posterior portion gives the sensation of stony hardness. It feels flat rather than spheric. It is just beneath the capsule, more superficial than deep and it has a sharp edge or corner. It is perceived best with the patient leaning forward with hands on a chair or elbows on a table, feet apart. Local lesions of inflammation are rounded or nodular and an x ray picture of the area is always indicated in order to rule out the presence of stone as the cause of the induration. When the observations are characteristic or suggestive enough, the patient should be prepared for the perineal operation, at which the area is exposed and a biopsy should be taken and examined immediately by frozen section. If positive, radical removal is completed. Associated enlargement can be enucleated or if it is small a transurethral section can be done at once through an opening in the urethra before closure of the perineum. Needle biopsies are misleading and have been largely abandoned. Primary lesions which cannot be palpated per rectum may be discovered by microscope study of material removed at transurethral resection or of the specimen after penile or suprapubic enucleation for enlargement. These cancers invade the enlargement at its periphery. They start in the parenchyma of the gland compressed by the enlargement to form its false capsule. Resections should put aside for particular microscopic search the material removed from the deeper peripheral portions of the enlargement.

Many writers believe that enlargement is never a focus of origin for carcinoma of the prostate. Even

If this is only partially correct, every suprapubic and perineal prostatectomy should be followed by a careful search of the surface of the specimen and of the cavity left after enucleation, and a biopsy with frozen section of any areas at all suggestive should be made. A cure by radical removal is then possible.

The evidence now available indicates that discovery of cancer by early diagnosis should be made while it is limited within the capsule of the prostate, that radical surgical intervention at this time will cure over 50 per cent of the patients, and that to increase the number of early diagnoses above the present dismal 5 per cent is a worthy effort.

It is evident also that benign enlargement and carcinoma are distinct and separate lesions of the prostate, even though they commonly occur together.

ROBERT O. BRADLEY, M.D.

Retropubic Extravesical Prostatectomy Millin's Operation Technique and Indications (*L'opération de prostatectomie rétro-pubienne extra vésicale. Operation de Millin Technique et Indications.*) R. GOUVERNEUR, P. ANTOULET, and A. DUBOIS. *J. chir. Par.*, 1947 63 425

Seventy prostatectomies by Millin's method have been performed by the authors. Two fatalities occurred and in 1 case incontinence developed but healed spontaneously within a year. In 5 patients secondary cystostomies, and in 2 others secondary endoscopic resections, were required. In 12 patients primary and secondary hypogastric fistulas followed the operation and closed within 20 or 30 days after insertion of a retention catheter. The first operation was performed more than a year prior to the publication of this article and so far no undesirable late sequelae attributable to the intervention have been noticed.

The authors performed the operation on 2 patients who had had cystostomies. A retention catheter was introduced through the urethra after a débridement of the margins of cystostomy. Both patients recovered but the duration of the convalescence was not shorter than that usually observed after Freyer's operation.

Millin's operation offers certain advantages over the perineal prostatectomy: the prostatic gland is approached anteriorly which avoids injury to the rectum, and also to the verumontanum which may lead to sexual impotence. The danger of injury to the striated sphincter, with the resulting incontinence of urine, is also avoided.

The use of Millin's retractor greatly facilitates the operation. An electric knife and a suction apparatus are indispensable. The authors advocate spinal anesthesia. The patient is placed in a horizontal position with the head slightly lowered. The incision should not extend more than 5 or 6 cm. above the symphysis pubis. Pfannenstiel's incision may also be employed. The success of the operation depends upon good exposure. The capsule is incised in a transverse direction as high as possible usually about 0.5 cm. below the vesicoprostatic groove. One of the assistants

elevates the prostatic gland with two fingers introduced into the rectum. The digital enucleation of the adenoma starts at its lower pole. After a section of the vesicourethral mucosal cuff, the adenoma is removed. The posterior lip of the cervicovesical orifice is resected to prevent a stricture. A catheter is introduced into the bladder through the urethra. A rubber drain and sulfanilamide are placed into the wound which is then closed. The vasa deferentia are closed at the beginning or at the end of the operation.

The following postoperative complications may develop:

- 1 Displacement of the catheter or its occlusion by blood clots. To avoid this complication the catheter should be attached to the prepuce with a suture and it should be irrigated at frequent intervals. Sometimes a suprapubic cystostomy may be necessary.

- 2 Intravesical hemorrhage. If lavage of the bladder does not stop it cystostomy with or without packing of the cavity resulting from the prostatectomy should be done.

- 3 Formation of a suprapubic fistula which may develop soon after the operation or after removal of the catheter. The first type is caused by an insufficiency of the suture of the prostatic capsule and is of no great clinical importance. The second type can be cured by insertion of a retention catheter through the urethra. Incision through the capsule should be done with a scalpel, in preference to an electric knife to avoid a superficial necrosis of the margins of the wound. A good grade of chromic catgut should be used for the sutures. Finally the administration of plasma or amino acids to correct nutritional deficiencies helps to avoid the formation of a secondary fistula.

- 4 Retention of the urine can usually be avoided by wedge shaped resection of the posterior lip of the neck.

- 5 Incontinence of the urine can be prevented by sectioning the urethra with scissors to avoid laceration.

Millin's operation should not be performed in the presence of a urinary infection. The operation is indicated in the presence of an intraprostatic adenoma of medium size. It is very difficult to find a small adenoma and it can be removed more efficiently by endoscopic resection. Giant adenomas should be excised through the bladder. The operation is contra-indicated in obese individuals for technical reasons.

JOSEPH K. NARAT, M.D.

Misconception of the Gubernaculum Testis. L. J. WELLS and DAVID STARR. *Surgery* 1947 22 302

Because of the many descriptions in the literature of the gubernaculum testis there has been a great deal of confusion concerning it. The main object of the present study was to determine whether the gubernaculum could be identified in surgical patients. A second and related objective was to search for any discrete band of tissue which might account for the widespread opinion that the gubernaculum

extends below that part of the inguinal bursa which normally becomes the spermatic sac.

Four patients were selected for careful study. During surgery the procedure was (1) to identify the inguinal bursa, (2) to search for a cord of tissue below its blind end (3) to open the bursa in order to note any manifestations of a gubernaculum on its posterior aspect, (4) to tag crucial portions of the bursa for the purpose of orientation in microscopic studies, and (5) to remove the bursa plus attached strands of tissue after freeing the testis. The surgical specimen thus obtained was fixed and studied microscopically.

It was found that sections of the gubernaculum could not be identified in any of the microscopic preparations of the 4 surgical specimens. Therefore only 1 of the case reports is presented in detail.

In this case, the patient was a white male 12 years of age with the main complaint of failure of descent of the testis bilaterally. One year previous he had received a series of 16 injections of gonadotropin without benefit. The patient's father and 3 brothers each had unilateral failure of descent of the testis.

Physical examination revealed a well nourished, well developed boy who was not acutely ill. The examination was negative save for a bilateral cryptorchidism and a left inguinal hernia. The left testis could be felt high in the inguinal canal but the right testis could not be palpated at all.

Surgery was done on July 1, 1946 and the following observations were made. The inguinal ring was visible as soon as the skin and subcutaneous tissues had been incised. A structure in the inguinal canal, subsequently identified as the testis, could be moved upward and downward by exerting manual pressure, but it would not pass through the external ring. The first indication of an inguinal bursa to appear was an indistinct outline of its fundus. Below the fundus it was impossible to see or to palpate any cord of tissue which might be said to resemble a gubernaculum.

When the bursa was opened the testis could be seen through its thin covering of peritoneum. A gloved finger in the peritoneal sac could enter the abdominal cavity by passing through the patent orifice of the bursa. Extending down from the tail of the epididymis was some unknown retroperitoneal structure that elevated the peritoneum to produce a longitudinal ridge. Aside from its narrowness, this ridge looked somewhat like that caused by a gubernaculum. It was tagged by means of a thread then this structure the part of the bursa distal to the testis, and the attached "ligament" were excised as a unit and placed in fixing fluid.

In microscopic studies of transverse sections of the bursa, the 4 layers of its wall were observed. The most distinct ones were the peritoneal and the cremasteric. Since a gubernaculum, like a testis, is a retroperitoneal structure, the internal spermatic layer is the one which should be expected to contain it. Despite most careful search no trace of a guber-

naculum could be found. Transverse sections of the tissue tagged by means of thread showed that the ridge of peritoneum observed during surgery was caused by blood vessels in the subperitoneal layer.

A block of tissue including the fundus of the bursa and the upper part of the attached "ligament" was sectioned serially and vertically. The sections showed that the "ligament" consisted of areolar tissue, fat, and small blood vessels.

In this case, it is clear that the "ligament" created by blunt dissection should not be called gubernaculum testis. On the posterior aspect of the internal spermatic layer of the bursa where a gubernaculum, if present, should be expected to lie, none could be found. These observations, however, should not be taken to mean that a gubernaculum could not be identified in all of the patients with an undescended testis; they are evidence against the common notion that a place to look for one is below the bottom of the bursa.

In conclusion the authors state that they were unable to identify a gubernaculum in any of 4 selected patients who were subjected to orchiopexy. The notion that it may be found below the fundus of the inguinal bursa in such patients is due to a misconception. If present, it should lie on the posterior aspect of the bursa and in the internal spermatic layer.

R. O. BRADSHAW, M.D.

On Malignant Tumors of the Testis. See GORDON GORDON TAYLOR and NORMAN E. WYNDHAM. *Ann J Surg* 1947 35:6.

The authors describe their experience with over 700 patients suffering from primary malignant neoplasms of the testis. Secondary malignancies are rare—only about 50 having been recorded in the literature. Metastatic carcinoma of the epididymis is still more exceptional—only 3 cases having been reported.

The authors distinguish 3 main types, namely the teratoma and the seminoma which can be easily recognized grossly; these tumors should be confirmed microscopically. Of 688 cases of testicular tumor, 461 (67 per cent) of the tumors were seminomas while 227 were regarded as teratomas. Chorioncarcinoma accounted for a little more than 1 per cent of the lesions, while sarcoma was very rare.

Seminoma is a seminal carcinoma and is unrelated histogenetically to teratoma. Willis believes that (1) transitions from seminal tubules to tumor can often be traced, and the appearances cannot be explained by secondary invasion of the tubules. (2) serial sections of seminomas, even small ones, show no teratomatous elements. (3) undifferentiated embryonic epithelial tissue is a frequent component of malignant teratomas. (4) when genuine seminoma and teratoma coexist in one testicle there is often distinct separation of the two neoplasms by testicular tissue or a fibrous capsule.

The radical operation is today employed under exceptional circumstances by a few surgeons. Even Hlman has recently performed a radical operation after irradiation in 3 out of 58 cases. Nowadays the

operation of choice is a simple mundane surgical exercise akin to that performed with consummate skill and dexterity by veterinary surgeons. Simple excision of the malignant testis should be combined with irradiation. This therapeutic combination has improved the prognosis. **ROBERT TUCKER, M.D.**

MISCELLANEOUS

Glandular Metaplastic Malignancy W. E. KIRKIDGE, JOHN C. HENNINGSEN, and MARK WHITEHEAD *J. Urol.*, Balt., 1947 58 282

Tumors in the urinary tract which contain glandular elements are not commonly seen but when they do occur they present certain practical and theoretical problems as to (1) whether the glandular elements represent metaplasia of transitional epithelium to glandular epithelium (2) whether the lesion is primary in the urinary tract or metastatic from the intestine or other glandular organs, and (3) whether the tumor arises from known glandular elements at the attachment of the urethra or around the urethral neck.

Transformation of the urinary epithelium from transitional to glandular type is known to occur in

ectrophy of the bladder and is said to take place in cystitis cystica. Metaplasia of this type in tumors was described by Stoerck as early in 1899, and in 1907 Stoerck and Zuckerkandl called attention to the similarity between the glandular tissue of tumors of the bladder and the mucosa of the large intestine.

In a recent review of the literature Foot gives an excellent discussion on metaplasia of urinary tract epithelium and reports 3 cases the metaplasia occurred in the epithelium of the renal pelvis in 1 case and in the epithelium of the bladder in the other 2 cases. In 1 of the latter 2 cases a malignant tumor (adenocarcinoma) was found.

The authors report 4 cases of glandular carcinoma of the urinary tract to illustrate the difficulty of determining whether an adenocarcinoma is primary or secondary in this location. In 1 case the tumor of the bladder was probably metastatic from a carcinoma of the colon. In 2 cases the adenocarcinoma probably arose from plaques of urinary tract epithelium which had undergone metaplasia to the secretory type. In 1 case metaplasia of the epithelium to the secretory type evidently occurred in an infiltrating transitional cell carcinoma.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

On the Problem of Trauma and Aseptic Osteonecrosis. IVAN HENRIKSSON. *Acta radiol* Stockh. 1947 8 357

Aseptic osteonecrosis may be caused by a trauma, or there may be a predisposing factor of some kind. In trauma, the fracture or a vascular disturbance alone may be responsible for the aseptic necrosis or the fracture and a vascular disturbance may be responsible jointly. The possibility that the predisposing factor may be localized in the bone nucleus or in the vasomotor nerves of the autonomic nervous system is considered. Three case histories are presented in detail.

The first case was an injury to the elbow and resulted in an aseptic necrosis in the capitellum and in the head of the radius. The second case was a fracture of the epiphyseal nucleus of the head of the radius and a fracture of the metaphysis. In this case, Schlatter's disease developed shortly afterward. In the third case, osteochondritis dissecans occurred in the lateral malleolus after trauma to the ankle.

In the cases in which an x-ray examination was made immediately following the injury a primary fracture was excluded. Thus, it is assumed that the trauma gave rise to a vascular disturbance which subsequently caused necrosis. There was no indication in any of these cases that there are any predisposing factors. RICHARD J. BENNETT JR., M.D.

Generalized Lipoid Granulomatosis. TORFINN DREISAD. *Acta radiol* Stockh. 1947 18 269.

A case report is presented of a man 55 years of age whose condition was diagnosed as congenital syphilis and leg ulcers. At another time a diagnosis of peritonitis and osteomyelitis was made. Multiple operations were performed on several bones of which the microscopic examination showed no indication of tuberculosis or syphilis. Subsequent multiple fistulas occurred in other portions of the body. At the age of 37 he had developed a fracture of the left upper arm. Between the ages of 50 and 55 he was given extensive treatment because of an ulceration of the right leg. In other words, many variable diagnoses were made over a period of years.

The author believes that osteitis fibrosa generalisata must be considered as a diagnosis, and he discusses Albright's disease also. In the x-ray department, it was concluded that this case was probably one of generalized xanthomatosis or more clearly termed, lipoid granulomatosis which is a form of Hand-Schüller-Christian's disease. The blood cholesterol showed high normal figures. From the high cholesterol figures and study of the clinical course in retrospect the diagnosis of xanthomatosis was made. RICHARD J. BENNETT JR., M.D.

Multiple Myeloma: A Survey Based on 25 Cases, 15 of Which Came to Autopsy. LOUIS LOEWENTHAU and HENRY L. JAFFE. *Arch. Path.*, Chic., 1947 44: 307

Multiple myeloma is a clinically and anatomically distinctive malignant disease of the skeleton apparently arising from the myeloid formative tissue. It is somewhat more common in males and in the fifth and sixth decades of life although it is not uncommon in the thirties. A few unequivocal cases have been reported in adolescents. In some cases the disease may be localized to a focus in one bone only for years. Although the bony framework may be riddled with foci of myeloma, it is only infrequently that gross myelomatous foci are found in the viscera and other extraskelatal parts. In some cases myeloma cells invade the blood stream and may create a leucemic blood picture (so called plasma cell leukemia).

The patient usually presents himself with a complaint of pain, especially of the back and thorax, often vague and generalized and accompanied by a feeling of weakness. The weight loss is usually substantial. Pathological fracture of the spine or long bones is common. With involvement of the lumbar region scoliosis was a common symptom. Sometimes a palpable tumor of an exposed bone such as a rib or clavicle is the presenting complaint. The course of the disease varies a great deal. The average period of survival following the onset of symptoms was about 3 years, although 2 patients survived 9 years and another is still alive 10 years after the onset. Long periods of remission are apparently spontaneous and not related to treatment.

The roentgen picture of multiple myeloma varies. In advanced cases many bones, including the calvarium, are riddled by osteolytic defects. In other cases (when myelomatous infiltration of the bone marrow is diffuse) roentgen changes may be minimal. If the infiltration is generalized marked anemia may result. Sternal bone marrow studies should be made whenever the presence of myeloma is suspected, and especially when biopsy of some obviously affected bone is not feasible. Hypercalcemia (ranging as high as 18 mgm. per cent) is present in about one half of the cases, reflecting the lytic resorption of the bones. The kidneys in such cases tend to show deposits of calcium granules in the tubular epithelium and interstitial connective tissue, and renal failure may develop. It should be possible to distinguish this condition from hyperparathyroidism since the serum phosphatase activity tends to be normal no matter how extensive the skeletal involvement may be. Hyperglobulinemia (from 3 to 14 gm. per 100 c.c. of blood by the Howe method) is observed in about half of the cases. The serum albumin level is either normal or diminished, apparently because of loss of albumin through the damaged renal tubules. The presence in the urine of protein, giving the Benedict

Jones reaction is noted in about 50 per cent of the cases. Its excretion may be intermittent. Protein excretion in the urine very rarely occurs in other conditions (senile osteomalacia, gunshot wounds, polycythemia). Amyloidosis is noted in about 10 per cent of the cases and amyloid deposits may be found in great quantity in the skeletal connective tissue generally.

Cytologically multiple myelomas may be divided roughly into two groups (1) those in which the tumor cells are quite uniform, predominantly small and have a superficial resemblance to plasma cells (hence the term 'plasma cell myeloma') and (2) those in which the characteristic cell is considerably larger and more variegated. The authors emphasize the unity of multiple myeloma and explain cytologic variations within them as expressions of their relative maturity or immaturity. The identification of the common ancestral cell of multiple myeloma is still a moot point, but this is probably of myeloid formative or hematic origin. Since multiple myeloma is such a distinctive disease entity clinically and anatomically it seems unreasonable to attempt to subclassify it into plasma cell myeloid erythroid and lymphoid myeloma.

Problems in therapy are concerned mainly with relief of the distressing bone pain, general supportive measures, and the care of such complications as pathological fractures and cord compressions. X-ray therapy may relieve the bone pain although it apparently has little influence on the course of the disease. Radioactive phosphorus sometimes results in subjective improvement, although it probably is not as effective as roentgen therapy and may produce a dangerous leucopenia and thrombocytopenia in some cases.

Stilbamide and 'pentamidine' in conjunction with a diet low in animal protein have been advocated. But palliation only is claimed for these drugs and they are not without distressing side effects.

Blood transfusions should be given for marked anemia. Laminectomy (followed but not preceded by roentgen therapy) may permit recovery of function for a number of years when transverse myelitis results from extradural compression.

VERNON C. TURNER, M.D.

Benign Central Cartilaginous Tumors of Bone.

BRADLEY L. COLEY and ANTHONY J. SANTORA, *Surg. Gory.* 1947 22 411

In a study of the records of 22 central chondromas the authors concluded that there may be a long latent period during which the presence of the lesion is not suspected. Usually the tumor is noticed between the ages of 10 and 30 years. It appears more commonly in the long bones. Both sexes are equally affected. About one-third of the cases present involvement of the phalanges. This lesion is the most frequent tumor found in that location.

A simple chondroma may be completely symptomless. When it has altered the contour of the bone the patient may notice swelling or deformity. Pain

when present is generally inconstant and mild. Disability is infrequent. Pathologic fracture especially in phalangeal chondromas is often the incident which precipitates recognition of the condition. The trauma which results in the fracture is often trivial and nearly always less severe than that which is responsible for simple fractures through normal bone.

Grossly, the tumor lacks the appearance of tissue seen in simple cysts, giant cell tumor or fibrous dysplasia. It presents a solid whitish firm mass completely filling the cavity and has a slightly gritty feel when attempts are made to remove it with the curette. At times calcific particles are seen and felt, but the purely fibrous quality of fibrous dysplasia, the vascular reddish nature of giant cell tumor and the fluid filled spaces of simple cyst are lacking. Myxomatous changes are not uncommon and it is probable that the extremely rare cases of pure myxoma of bone which have been reported are examples of degeneration of a central chondroma. While not encapsulated, the lesion is usually rather definitely circumscribed and for this reason it is possible to remove it completely by painstaking curettage. The cells are usually rounded but may vary in size and may become fusiform or stellate. Calcification may be seen in scattered areas.

In the x-ray film it is often possible to confuse the picture with that presented by bone cyst, giant cell tumor and nonosteogenic fibroma of bone. The treatment of central chondroma is surgical. For lesions in the rib, fibula, and scapula resection of the entire tumor bearing area is indicated. When the involved area constitutes a considerable proportion of the thickness of the shaft of an essential long bone (femur, humerus, tibia) it is important to utilize bone chips from the ilium or pencil grafts from the tibial cortex to fill the defect and to assure more complete and more rapid bone regeneration.

In this series of 22 patients there were only 2 recurrences of the tumor. Both of these were successfully managed by reoperation. Roentgen therapy is not satisfactory.

The authors state that the benign chondroblastoma is not a giant cell tumor and that it belongs properly with the tumors of cartilaginous origin. Jaffe and Lichtenstein considered it to be distinct from giant cell tumor and not even a variant of it. They termed it a benign chondroblastoma. This lesion is not confined to the upper humerus as is noted in Codman's original description of the tumor. Roentgen therapy may be successful in chondroblastoma in contrast to its effect on central chondroma. Chondroblastoma more closely resembles giant cell tumor than does central chondroma. At times chondroblastoma presents roentgen evidence suggestive of a malignant bone sarcoma. Pain and swelling at the site of the lesion is the usual complaint. Trauma has not been shown to be of etiologic importance although an injury to the part might well attract the patient's attention to it.

C. FRED GOERINGER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Diagnosis and Treatment of Recurrent Dislocation of the Shoulder ROSS ROBERTSON and W J STARK. *J Bone Surg* 1947 29: 197

Twelve patients with anterior dislocation and 3 with posterior dislocation of the shoulder were treated by open operation. All of the injuries were traumatic in origin and there had been multiple recurrences. These operations were performed from 7 to 18 months previous to the publishing of this article. Thirteen of the 15 patients have returned to work, and most of the patients do hard labor. There has been an average of from 10 to 15 degrees of limitation of external rotation and abduction in the anterior dislocations and a similar limitation of internal rotation and abduction in the posterior dislocations.

The author suggests that through a posterior lateral incision the acromion be divided and rotated outward to give free access to the joint. The operation consists mainly in locating the lateral edges of the ruptured capsule and suturing it securely to the edge of the glenoid. The structures are then anatomically put back into normal relationship.

RICHARD J BROWNE, JR., M D

Metacarpal Reconstruction. J WILLIAM LITTLE. *J Bone Surg* 1947 29: 7-3.

The main reason for metacarpal reconstruction is the restoration of function. The success of the operation is in direct proportion to the accuracy with which the graft is fitted to the carpal, metacarpal, or phalangeal fragments. If only the head of the metacarpal remains, it can be stabilized by extending the graft into the carpus. If only the base remains and the finger is preserved the graft can be fused to the proximal phalanx at 30 degrees of flexion.

When there are multiple metacarpal defects multiple bone grafts may be placed in one operation. If the proximal portion of the first metacarpal has been destroyed the distal fragment may be fused to the carpus if the thumb is placed and maintained in a functional position. If an injury should involve the distal portion of the first metacarpal with extension into the metacarpophalangeal joint, a fusion of this joint at approximately 30 degrees of flexion is recommended. At the time of operation, all the scar tissue is resected. The proximal fragment is recessed with an osteotome at an angle of approximately 30 degrees. The distal fragment is cut transversally and the medullary cavity is opened to receive the doweled end of the graft. The defect is carefully rebuilt with a graft measuring at least $\frac{3}{4}$ inch longer than the estimated defect. The dowel is formed at one end of the graft and the other end is cut obliquely at 30 degrees. The ends are carefully closed over the graft. The various steps of the operative procedure are illustrated in the original article. Following the operation a plaster-of-Paris cast is applied. A period of 3 months is required for good union. Forty-four patients, with a total of 56 individual grafts have been

operated upon. Two small grafts were absorbed and 1 graft failed to unite.

RICHARD J BROWNE, JR., M D

Ambulatory Treatment of Hallux Valgus. EDWIN L. CONYER and WILLIAM J SCHWARTZ. *Surry*, 1947 22: 545.

A total of 24 patients were subjected to one or more operations for hallux valgus in the operating room of the outpatient clinic and then permitted to go home immediately by whatever transportation they could obtain. There were no complications. The results which were obtained were definitely better than those which had been observed in patients whose care had included 3 or 4 weeks of hospitalization with complete immobilization. These patients suffered minimal pain and all of them returned to the clinic walking surprisingly well and with an excellent range of motion in the metatarsal phalangeal joint. Local novocaine anesthesia was used.

In another series of 17 patients who were hospitalized for hallux valgus and bunions an additional 26 operations were performed. The patients who were operated upon under local anesthesia were encouraged to walk about their rooms immediately after the operation and were given bathroom privileges. Because of persisting anesthesia, they experienced no pain. In summary the author states:

1. The hallux should be splinted by means of corrective bandaging, without rigid fixation, following the operation. Multiple layers of bandage are essential if correction of the hallux valgus is to be maintained while ambulation is permitted.
2. Walking with full weight bearing is begun immediately when the operation is done under a local anesthetic, and on the day following the operation when it is carried out under general anesthesia.
3. The patient may be discharged from the hospital from 2 to 4 days after operation.
4. The original dressing should be changed and the sutures removed 24 days after operation.
5. The functional splinting by corrective bandaging should be continued for an additional 2 weeks.
6. Patients may be encouraged to resume their normal activities at the time that the bandaging is discontinued.
7. After bandage splinting is discontinued the foot should be soaked in warm, slightly soapy water for 30 minutes each day. While in the warm water the toe should be actively exercised.
8. Low heel, soft leather oxford shoes with a stiff shank, straight inside last, and metatarsal pads should be worn for at least 3 months.

C. FRED GORING, M D

Pseudarthrosis Resulting from the Use of the Intramedullary Nail of Kuntscher (Primo trattamento di terapia delle pseudartrosi col chiodo endomidollare di Kuntscher). PASQUALE DEL TORRE. *Gazz. Med. Ital.* 1947 31: 373.

The author presents a review of the history of internal fixation of fractures from 1886 to the advent

of the Knuetscher nail in 1940. He discusses the theoretical and practical advantages of the use of the intermedullary nail of Knuetscher. He also presents some of the disadvantages of this method in 4 case reports in which nonunion resulted. Three of these cases involved the femur and 1 case the humerus. These cases were reported as a warning against the optimistic trend of thought of some European and American surgeons in regard to this method.

CARLO SCUDERI, M D

FRACTURES AND DISLOCATIONS

The Olecranon Process. FRANCIS M. McKEEVER and RONALD M. BUCK. *J Am Med Ass* 1947 135:1

The removal of the fractured fragments of the olecranon process of the ulna is recommended when there is comminution of the fragments. This does away with the long healing process with considerable extra bone formation and usually involves some limitation of motion.

Total excision of the fractured fragments was carried out in 10 patients. In 7 patients there were old ununited fractures. The average restriction of flexion in the elbow in these 7 patients was 38 degrees. The average loss of extension of these same patients was 28 degrees. All of the patients experienced less pain after the operation and all of them had an increase in the range of motion of the elbow. The average improvement in motion was 57 degrees. Three patients believed that they traumatized their ulnar nerve more easily than before the excision of the olecranon. Stability of the elbow joint is dependent on the coronoid process and the distal vertical face of the ulna. If the fracture of the ulna is distal to the coronoid process the fragment should not be excised.

The operation consists of a 20 cm. curved incision over the olecranon. A wide dissection of the tissues is carried out the ulnar nerve is rerouted a transverse incision is made through the periosteum of the ulna distal to the site of the fracture and a flap is turned onto the triceps. The fractured fragments are excised from this flap. The sharp edges of the fractured bone are rounded the forearm is put into extension and the flap of the periosteum is drawn tight and sutured to the tissues of the forearm. A molded plaster splint is applied with the arm in moderate flexion for 3 weeks.

All patients were greatly benefited both subjectively and objectively. None had any instability of the elbow.

RICHARD J. BENNETT JR., M D

An Operation for Old Unreduced Bennett's Fracture. JOHN R. VASKO. *J Bone Surg* 1947 29 753

Three cases of old unreduced Bennett's fracture were treated by the suggested method. The greatest improvement following this procedure has been in the grip of the hand. In other cases in which the fracture was not reduced the grip has been materially weakened.

The operation is performed by making an incision over the dorsum of the base of the first metacarpal

the incision being carried down to the bone and the opponens pollicis and flexor pollicis brevis are then stripped off. Another small incision is made into the capsule. The small fractured fragment is located and two small drill holes are placed through the fragment. A third drill hole is made in the base of the metacarpal. The normal relationship is restored and the fragments are held in place by means of passing a No. 24 cotton suture through these holes. After closure a gauntlet type of cast is applied. The cast is left on for 4 weeks after which active motion is encouraged. The results are reported to be good.

RICHARD J. BENNETT JR., M D

ORTHOPEDICS IN GENERAL

Management of Hand Injuries. F H McC. CALLOW. *Med J Australia* 1947 2 349

Several factors contribute to unsatisfactory management of hand injuries. Little attention is given to teaching the subject in classroom lectures and in textbooks the injuries are often regarded as trivial, although from a functional viewpoint, fractures of the fingers may result in more disability than a fracture of the femur. A hand injury is a surgical emergency.

Examination of the injured hand calls for time and care. Every piece of skin should be saved if possible. The most common cause of crippling of the hand is scarring which always results when wounds granulate in. One should test for injury to the various individual nerves and tendons in every case.

Thorough cleansing of the hand and wound in the operating room under general anesthesia is of the greatest importance. After debridement of the wound and careful suture of severed nerves or tendons the wound must be closed if possible. If the skin edges cannot be drawn together the author recommends the use of a Thiersch graft immediately. Covering the wound in this manner promotes rapid healing and prevents infection, and the percentage of "takes" is high. In suturing the wound it is better to use too many rather than too few sutures. Fine needles and fine nonabsorbable suture material (silk, cotton, wire) are essentials. Skin hooks are preferable to forceps in handling the skin. Splinting is usually maintained for 3 or 4 weeks, but should be immobilize as few joints as possible. Nonsplinted joints must be used.

Rehabilitation of the injured hand is best accomplished by normal use, instituted as early as possible.

VERNON C. TURNER, M D

Management of Hand Injuries, Especially the Treatment of Injuries to Bones and Joints. LESTER J. WOODLAND. *Med J Australia* 1947 2 351

Mangled fingers and hands result in more permanent deformities and in far greater economic loss to the patient than major fractures of the long bones. Of all industrial accidents injuries to the wrist

hand and fingers account for one third of the number and about one-fifth of the cost. Of 50,000 injuries resulting in permanent partial disability 45 per cent involved the hand. Twenty-seven per cent of the hand injuries in industry cause some permanent disability. Roughly 1 in 4 of all hand and finger injuries become infected—a frequency 4 times greater than that found in injuries of other parts. Finger fractures cost about as much in compensation as do fractures which involve the long bones.

Solving the problem of hand injuries is like working a puzzle. If one factor is not correct, the puzzle is unsolved. In hand injuries and particularly finger injuries if one tissue—be it skin, tendon, ligament, bone or joint—is not restored, the result is partial or complete failure to prevent permanent disability.

Fractures of the bones of the hand usually heal in about 3 weeks, and the author believes that if fixation is removed earlier the position is apt to be lost and disability will result. Nonunion is very rare. Decalcification may result from reflex hyperemia due to pain or from infection. Fractures must be accurately reduced since the mechanism of the hand is intimately and compactly fitted together. Fingers splinted in extension will stiffen and full flexion of the other fingers will be impossible. Edema from whatever cause must be very actively treated, for fibrin will be deposited between all the tissues and produce fibrosis. Disease of the hand alone may cause edema. One must be a fanatic in the crusade against edema in order to secure good results. Occupational therapy of the remedial type is of greater help in rehabilitating the patient than routine physical therapy. Passive exercise should not be used in any of these cases.

If it is necessary to use traction (preferably through the pulp of the finger) it must be observed daily to see that it remains effective.

VENKOW C. TUDOR, M.D.

Correction of Retractions of Extremities by Slow, Bloodless Procedure (Corrección de las retracciones de los miembros por procedimientos lentos—no cruentos) JOSÉ M. JOROX and JOSÉ A. B. BÉLIZO. *Rev. Acad. argent. cir.* 1947 3:56.

Deformities of the extremities attributable to retraction of certain muscles, usually the flexors, and those caused by burns, paralysis of various origins (such as infantile paralysis) congenital myopathies and contractures which are sequelae of rheumatic polyarthritis may be of such severity that an operation is impossible or dangerous. In such cases a slow bloodless correction is recommended by the authors. Uninterrupted or intermittent traction may be applied. The authors usually employ skeletal traction being careful to use as little force as possible in order to avoid undesirable reactions.

Excellent results have been obtained in 3 patients. In the first, a young man of 19 years, a deformity of both hands and of the left lower extremity had been caused by a burn. The deformity involved both lower extremities in the second patient, a girl of 17 years, and was caused by infantile paralysis. In the third patient, a boy of 11 years, incomplete quadriplegia either of a congenital character or due to a myelopathy was present. In the last 2 cases the application of casts and conservative surgery in the form of tenotomies and osteotomies were supplemented by gentle traction. In this manner a rehabilitation of the patients was obtained.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

The Action of Heparin on Experimental Venous Thrombosis. LEO LEOWE, EDWARD HIRSCH, DAVID M. GRAYELL, and FLORENCE KASHDAN *Surgery* 1947 22 746

The authors, because of the variation of opinion as to the effect of heparin on preformed clots, elaborate upon the in vivo action of heparin on such clots. Heparin in vitro fails to exert any action on clots; heparin in vivo has on occasion resulted in disappearance of the clots. The recapitulation of previously recorded experiments was as follows: (1) if heparin was given previous to trauma and continued for a variable period afterward, thromboses were infrequently observed; (2) heparin administered up to 3 days after trauma caused disappearance of the clot in a considerable percentage of cases; (3) heparin administered when the clot was organized resulted in no demonstrable dissolution of the clot.

With the use of rabbits, the authors induced thrombosis in the jugular veins by mechanical means. After a variable control period one vein was removed from the rabbit for microscopic examination and then heparinization with a heparin Pitkin menstruum preparation was carried out for 6 to 14 days. The second jugular vein was then removed for study.

From this series of experiments the following conclusions have been drawn: (1) patency can be re-established in a number of experimental veins even as long as 6 days after a clinically visible and microscopically acceptable thrombus is present; (2) the extent and apparently the speed of recanalization is enhanced by the use of heparin; (3) when the vein is so occluded grossly as to preclude the resumption of clinical patency, recanalization is still greater in degree and extent under heparin therapy; (4) in the presence of occluded veins which cause definite obstruction to circulation, the opening of adjacent collateral venous channels is so extensive in the presence of heparin that the combined cross sectional area of the collateral system appears as great, if not greater, than that of the original vein.

EDWARD H. CAMP, M.D.

Post Thrombotic Sequelae of the Lower Extremity Treatment by Superficial Femoral Vein Interruption and Stripping of the Saphenous Veins (A Preliminary Report). ROBERT R. LINTON and IRAD B. HARDY, JR. *Surg. Clin. N. America* 1947 27 1171

The authors report a series of 34 cases of ulcer and edema of the lower extremity due to incompetence of the valves of the communicating and deep veins, which they treated by interruption of the long saphenous vein and stripping combined with interruption of the femoral vein distal to the junction of the profunda femoris vein. In every case the valvular

incompetence and circulatory defect was due to thrombophlebitis with recanalization, a definite history of thrombophlebitis being elicited in all but 3 cases. The Trendelenburg test performed with the tourniquet below the knee, revealed incompetent deep and communicating veins in all cases.

The authors describe the procedure and emphasize the necessity of determining venous pressures in the superficial femoral vein distal to a temporarily applied occluding ligature. Measurements are taken with the vein patent, with the vein occluded, and then with the long saphenous vein occluded, should the venous pressure exceed 30 cm. of water with both veins occluded, the operative occlusion of the femoral vein and ligation and stripping of the saphenous vein simultaneously are contraindicated. The authors believe that it is better in such a case to perform only one step of the procedure and to complete it at a later date when the venous pressure has fallen to more normal levels. Emphasis is also placed on the necessity of stripping the saphenous vein from its femoral junction to below the internal malleolus.

The results obtained were encouraging, with fallure of ulcer recurrence in all but 1 case, and improvement of edema in the majority of cases, as determined in a follow-up of from 2 to 14 months.

EDWARD H. CAMP, M.D.

The Therapy and Prophylaxis of Venous Thrombosis and Pulmonary Embolism. GORDON A. DONALDSON. *Surg. Clin. N. America*, 1947 27 1037

The therapy and prophylaxis of venous thrombosis and pulmonary embolism in the Massachusetts General Hospital, Boston, is producing results, as evidenced by an incidence of 3 fatal pulmonary emboli for every 1,000 operations there in 1945 as compared with slightly less than one per 1,000 operations in 1946.

Rational treatment of established thromboembolic disease may take one or more of three forms: the use of anticoagulant drugs, lumbar sympathetic block, or deep vein interruption. The use of heparin and dicumarol is based primarily on the prevention of the extension of thrombosis until such time as the established coagulum becomes more strongly organized to itself and to the vessel wall and until the patient is adequately ambulatory to insure a vigorous venous return. Lumbar sympathetic block rapidly and effectively increases venous return by interrupting reflex arterial spasm resulting from the irritating venous inflammatory process. Deep vein interruption performed above the level of the thrombosis precludes the further propagation of the thrombus and fatal embolism. Statistics of femoral vein interruption at the Massachusetts General Hospital are presented.

A controlled study in the prophylaxis of post-operative thrombophlebitis and pulmonary em-

bolism was carried out on comparable surgical services in the Massachusetts General Hospital during 1945-1946 the middle-aged patients in the study group receiving dicumarol routinely in the older aged group prophylactic superficial femoral vein interruption was carried out. The control group received no dicumarol and vein interruption was done in only a few instances in which patients developed recognizable thromboembolic disease. No fatal emboli occurred in the study group of 2,932 patients, while 6 fatal emboli occurred in the control group of 1,896 patients. The technique of the surgical procedure is outlined. EDWARD H. CAMP M.D.

Traumatic Arterial Vasospasm. PHILIP S. FOSTER.
N. England J. M. 947: 237, 1955.

This article is concerned not with the cases of subtotal ischemia in which immediate viability of a part is threatened, but rather with the larger group of traumatic cases wherein the persistence of low grade arterial spasm is likely to cause nutritional changes adversely affecting the functional result. The author contends that in many of these cases of low grade spasm, poor results can be avoided with rational specific therapy.

The incidence of arterial spasm does not parallel the severity of the original wound. Spasm is found more often with the smaller, quickly closed wounds, which suggests that tension is a factor. Injury to large arteries or nerves is not necessarily a part of the mechanism producing arterial spasm. A certain individual susceptibility is thought to be present. Diffuse tissue damage due to the concussive effect of explosive missiles is often a causative factor. The clinical picture includes local discomfort and resistance to function. The patient shows decreased surface temperature, blotchy cyanosis, and diminished peripheral pulses.

A penetrating low grade ischemia causes trophic changes that materially impair the functional result. Two cases of traumatic arterial vasospasm in which sympathetic block resulted in clinical improvement are presented. W. FOSTER MONTGOMERY M.D.

Surgical Cure of Innominate Aneurysm. HARRIS B. STUMACKER, JR. *Surgery* 947: 2, 1959.

Because of the few reported cases of surgical cure of innominate aneurysm, and because it presents such a difficult therapeutic problem, the author presents a report of the surgical cure of an aneurysm of the innominate artery in a soldier.

A summary is made of the 38 reported cases of attempted surgical treatment of innominate aneurysms, and essential points of analysis of these cases are selected as follows: (1) adequate exposure is essential, (2) hemorrhage at the time of operation or secondarily is the greatest attendant risk and commonest cause of death, (3) cerebral difficulties can be reduced to a minimum by repeated preoperative carotid compression, (4) the best surgical procedure from the standpoint of safety to the patient and likelihood of cure of the lesion is proximal and distal

ligation combined, when feasible, with excision of the sac or evacuation of its thrombus division and transfixion of the arteries rather than ligation in continuity is the procedure of choice, (5) for those cases involving the origin of the innominate artery wiring and coagulation, possibly combined with distal ligation, is probably the safest procedure offering the likelihood of a satisfactory result, (6) preoperative measures to increase collateral circulation are advisable.

EDWARD H. CAMP M.D.

The Clinical Behavior of Arteriosclerotic Aneurysm of the Abdominal Aorta: A Rational Surgical Therapy. ARTHUR H. BLACKBURN. *Ann. Surg.* 947: 26, 1955.

In a series of 35 cases of aneurysm of the abdominal aorta, reported from the Presbyterian Hospital, New York, the condition in 16 cases was due to arteriosclerosis, and in 6 cases, to syphilis. Vertebral erosion was noted in 4 of the patients with syphilis and in only 1 of the patients with arteriosclerosis. Aside from the fusiform nature of the arteriosclerotic aneurysms, a second factor was thought to be largely responsible for the rarity of the erosion, namely, elongation of the abdominal aorta. Angiostasis, with a buckling rather than a bending effect in the vessel, was noted in many specimens studied. This flexion angulation, the author thinks, may play a part in the development of the abdominal aneurysm. Because of the vertebral erosion and the pathology involved, the syphilitic patients showed a higher incidence and severity of pain. Attention called to the low incidence of pain and erosion with the sclerotic aneurysms. The appearance of deep-seated abdominal pain, low back pain, and pain radiating to the hips or legs, is a warning of impending disaster. Life-saving measures may be instituted even after signs of retroperitoneal hemorrhage.

The ideal surgical therapy for aneurysm entails cure with maintenance of blood flow through the affected vessel. This is accomplished by the electrothermic method herein described. Attempts to introduce a wire and induce clotting date from that of Moore in 1864. The author explains that the circulating blood exerts a pressure on the expanding aneurysm wall which varies with the square root of the surface area and the rate of blood flow. Clotting in turn offers the advantage of physical laws governing solids and usually clotting within the sac reduces the surface area to only that of a small area of the mouth of the sac. The rate of blood flow through the sac varies proportionately to the size of the mouth. The method of wiring and electrothermic coagulation is described in detail, and the method of determining and utilizing the rate of blood flow in the sac is explained. A technique with wiring is described for cure of fusiform aneurysm of the abdominal aorta and coagulation in conjunction with gradual endoarterial occlusion is described and discussed. Because of the factors tending to increase the incidence of aneurysm, this therapy is assuming more importance. W. FOSTER MONTGOMERY M.D.

Sympathectomy as an Adjuvant in the Operative Treatment of Aneurysms and Arteriovenous Fistulas. Sympathectomy Performed before or at the Time of Operation HARRIS B. SHUMAKER, JR. *Surgery* 1947 22 571

An experience with 303 cases of aneurysms and arteriovenous fistulas is reported. In the present series 290 patients were operated upon and 23 required no operative treatment because of cure of the lesions by thrombolysis. Seventy-eight sympathectomies were done before or at the time of operation. One additional sympathectomy is included in which the patient was thought to have an aneurysm, but proved to have costoclavicular compression of the subclavian vessels simulating the signs of aneurysm. Of these 79 sympathectomies, 34 were dorsal and 55 lumbar. No deaths and no serious complications occurred. Lumbar sympathetic ganglionectomies were performed under spinal anesthesia through an anterior extrapertoneal muscle-splitting incision. The upper extremities were denervated by the pre-ganglionic operation of Smithwick performed under intratracheal gas-oxygen-ether anesthesia.

The majority of sympathectomies were carried out in patients with lesions of the larger peripheral arterial stems. Sympathectomy was performed in 25 of 57 cases of popliteal involvement (44 per cent) in 11 of 25 cases of axillary lesions (44 per cent), in 17 of 53 cases of femoral aneurysm or fistula (32 per cent) in 3 of 11 cases of subclavian (27 per cent) and in 5 of 33 cases of brachial lesions (15 per cent). A few sympathectomies were done in instances of involvement of the innominate or common femoral arteries. In 12 of 107 patients with involvement of vessels other than those mentioned, sympathectomy was performed (11 per cent). Altogether 76 sympathectomies were performed in 290 cases in which operative treatment of the aneurysm or fistula was necessary (26 per cent).

Sympathectomy was done in a larger percentage of arterial aneurysms (34 per cent) than of arteriovenous fistulas (22 per cent). This was particularly true in lesions of the axillary, femoral and popliteal vessels. Although this difference is primarily a reflection of the tendency to poorer collateral circulation in instances of arterial aneurysm, it is partly dependent upon the fact that associated nerve infarcts requiring operative treatment were twice as common in cases of arterial aneurysms as in those of arteriovenous fistula. Forty-eight per cent of the arterial aneurysms operated upon involved the subclavian, axillary, femoral and popliteal arteries in 33 per cent of the arteriovenous fistulas there was involvement of these vessels.

Sympathectomy was done on 39 patients because of poor collateral circulation determined principally by the reactive hyperemia test of Matas. In a number of these patients, in addition to evidence of poor collateral circulation there were other reasons why it was deemed advisable to make every effort to render the collateral circulation adequate rapidly. These were associated peripheral nerve lesions requiring

operative treatment (41 per cent) severe pain pronounced vasospasm, superficial gangrene and rupture of aneurysm. There were 25 patients in whom the previously poor results of testing collateral circulation became satisfactory after sympathectomy.

In most instances the operation upon the vascular lesions closely followed the sympathectomy. In all but 2 cases, cure of the aneurysm or fistula entailed ligation of the affected artery. In the exceptions continuity of the artery was preserved or re-established by ligation of the fistula or by vein graft to bridge the arterial defect.

One case of a popliteal arteriovenous fistula is cited and excision of the fistula was first done 3 weeks after the sympathectomy. Gangrene resulted which required amputation of the distal third of the foot. There were 14 cases in which sympathectomy failed to render the tests for collateral circulation satisfactory however there was considerable improvement. In 1 patient a satisfactory cure by thrombolysis occurred making operation unnecessary and in 9 patients the continuity of the affected artery was maintained or restored by ligation of the fistula, end-to-end suture or by vein transplant. In only 4 cases was it necessary to ligate the involved artery. In all cases an excellent result was obtained. In those cases in which the continuity of blood flow through the affected artery was successfully maintained there was, in addition, no fatigue on exercise unless such fatigue had been present before operation. In all cases the color and warmth of the affected hand or foot was observed during a prolonged period of precise occlusion of the artery with a rubber-shod clamp at the time of operation and in all but 1 case this period of observation showed that the collateral circulation was actually adequate. In many of the cases some anatomic condition was found at the time of exploration which explained adequately the reason for the false results of the tests carried out before operation.

In 10 patients sympathectomy was done because of the impossibility of testing the collateral circulation preoperatively due to inaccessibility of the vessel. The aneurysms were arterial in 6 cases and arteriovenous in 4. The author believes that the procedure was definitely helpful in some cases it undoubtedly prevented cold sensitivity postoperatively.

In 6 patients sympathectomy was done because of vasospasm. This was believed to be definitely beneficial.

In 7 patients sympathectomy was done because of causalgia, ischemic lesions, and other conditions. In 2 the procedure was carried out chiefly because of causalgia. Both were improved.

In 7 cases sympathectomy was done needlessly because of error in localizing the lesion. However the results are listed as excellent, and the mistake appears to have been in localization of the lesions. It is pointed out the arteriography could have been very helpful.

Sympathectomy was performed at the time of operation upon the aneurysm or fistula in 9 patients

for various reasons, and was beneficial in all but 2 cases. In these there was evidence of ischemic paralysis postoperatively from which recovery was complete in one of the cases.

Consideration is given to the influence of sympathectomy upon the two commonest functional disorders which follow the ligation of arteries for the cure of aneurysms and fistulas, namely decrease in exercise tolerance and sensitivity of the limb to cold. A careful review of the exercise tolerance in patients having lower extremity lesions showed it to be the same regardless of whether sympathectomy had been performed. Sensitivity to cold of varying degree followed operation upon the subclavian axillary and brachial arteries in which ligation was necessary or in which reparative procedures failed to maintain continuity of the vessel, in 5 of 18 patients in whom sympathectomy was performed before or at the time of operation, and in only 1 of 32 cases of popliteal, femoral, or common femoral lesions treated similarly. Of these 6 patients, cold sensitivity was present before operation in 2. On the other hand cold sensitivity was present after operation in 13 of 42 patients treated for lesions of the subclavian axillary and brachial vessels without sympathectomy and in 5 of the 65 patients with popliteal, femoral, or common femoral lesions. Eight of these 18 patients had some cold sensitivity before operation. Among those patients operated upon elsewhere, sensitivity to cold was present in 5 of 11 patients with aneurysms or fistulas of the main arteries to the upper extremity and in 9 of 30 with lesions of the main arteries to the lower extremity. Altogether 13.7 per cent of those 51 patients sympathectomized before operation upon the vascular lesions had sensitivity of the limb to cold.

Not infrequently sympathectomy was followed by a noticeable increase in the mural thrombus within the aneurysmal sac. Spontaneous cure occurs occasionally without sympathectomy in cases of both arterial aneurysm and arteriovenous fistula. This occurred in 11 of 225 cases studied. On the other hand "cure" by thrombosis occurred in only 2 of 78 patients sympathectomized; an incidence of 2.6 per cent. Thus it is difficult to be certain that the thrombosis is actually the result of the sympathectomy. The hypothesis offered by Gage, that the responsible mechanism is the decrease in peripheral resistance appears the most explanatory. In 1 case there appeared to be distal extension of the clot in a patient with an arteriosclerotic aneurysm of the popliteal artery.

LEROY J. KLEINERMAN, M.D.

Sympathectomy as an Adjuvant in the Operative Treatment of Aneurysms and Arteriovenous Fistulas. Sympathectomy Performed after Operation. HARRIS B. SHUMAKER, JR., *Surgery*, 1947 21: 597

The clinical material consists of 290 patients who were operated upon for aneurysms and fistulas, 13 patients in whom a satisfactory cure by thrombosis occurred and an additional 63 patients who had been

operated upon by others. Sympathectomy was done before or at the time of operation upon 76 of the 290 patients, and upon 1 of the 63 patients who had been operated upon by others and it was carried out in 2 of the 13 patients in whom a cure by thrombosis subsequently occurred. Sympathectomy was performed after operation in 19 of the first group and in 18 of the second. Sympathectomy was also done subsequently in one patient who had had a spontaneous cure.

The chief indications for operation in 39 cases were as follows:

1 Sensitivity of the limb to cold. There were 17 patients in this category: 9 had arterial aneurysms and 8 had arteriovenous fistulas. All the patients had annoying coldness of the affected hand or foot upon exposure to cold and most of them had cyanosis. All had discomfort during such exposure and the majority had some degree of numbness of the fingers or toes, and nearly all complained of stiffness of the fingers or toes. Increased resistance to cold was tested with sympathetic procaine anesthesia. Eight patients had associated peripheral nerve lesions. All but 2 patients obtained complete relief from cold sensitivity and definite improvement occurred in these.

2 Associated paralysis and impaired circulation. In 5 patients sympathectomy was performed in an attempt to improve impaired circulation, in order to afford maximal opportunity for repair of extensively damaged peripheral nerves. Improvement occurred in all cases. It was notable that in those cases in which it was thought the pressure of the aneurysm was partially responsible for the pain there was little improvement by merely operating upon the aneurysm.

3 Persistent edema. Six patients were operated upon for this reason. All had failed to improve under conservative measures and sympathetic block gave only temporary or no relief. In all there was improvement.

4 Ischemic lesions, causalgia, and other conditions. There were 11 patients in this group and in all the treatment by sympathectomy was beneficial.

BLOOD TRANSFUSION

Hemophilia: A Report of the Mechanism of the Development and Action of an Anticoagulant in 2 Cases. CHARLES O. CRADOCK, JR., and JERRY S. LAWRENCE. *Blood* 1947 2: 505.

Two cases of hemophilia are presented in which the development of a circulating anticoagulant was detected. This anticoagulant was demonstrated in the whole blood plasma, and serum in both cases. One of these cases has been previously reported by Lawrence and Johnson and a similar one was reported by Munro and Jones in 1943. Munro and Jones suggested that numerous transfusions are responsible for the development of this anticoagulant. Munro later showed by plasma fractionation that the anti-

coagulant activity was associated with the globulin fraction of the plasma, this is the gamma globulin fraction. Lawrence and Johnson found it to be heat stable and nondialyzable through colloidion.

Both of the authors' patients became refractory to treatment with either fresh whole blood plasma, or antihemophilic globulin (Fraction 1 of Cohn). In fact, the anticoagulant apparently made its appearance as a result of repeated transfusions or injections of antihemophilic globulin. The authors showed that antithromboplastin was not present in enough strength to explain the anticoagulant activity of the patient's blood. The anticoagulant in each case was shown not to inhibit any of the elements participating in the classical theory of clotting, i.e. prothrombin, thromboplastin, thrombin or fibrinogen. It was also demonstrated that this anticoagulant was not related to heparin in its mechanism of action.

Electrophoretic fractionation of the plasma was carried out and it was found that the anticoagulant was associated with the gamma globulin fraction of plasma. The demonstration of specific precipitin titers in the serum of each of these patients against antihemophilic globulin seemed to indicate that the mechanism of action of the anticoagulant was to inhibit the action of antihemophilic globulin. This was further substantiated by the in vitro inhibition of the ability of antihemophilic globulin to accelerate the coagulation time of ordinary hemophilic blood.

A hypothesis is presented to explain the appearance of the anticoagulant. It is believed that these 2 hemophiliacs are deficient in or lack antihemophilic globulin in their blood and hence repeated injections of the globulin either in the form of whole blood plasma, or Fraction 1 of Cohn resulted in 'isomunization' against the injected globulin. The resulting antibodies inhibited any antihemophilic globulin which may then have been injected which explains the refractory state exhibited by these 2 cases. Blood from these patients containing these antibodies likewise exerted an anticoagulant influence when added to normal blood by the same mechanism.

It is significant that the transfusion of washed red cells resulted in improvement in both of these cases.

LEROY J. KLEINWASER, M.D.

Studies on the Enigma of the Hemostatic Dysfunction of Hemophilia. ARMAND J. QUICK and WILIAM F. STAFF. *Am. J. M. Sc.* 1947 214 273

The deficient factor in hemophilia is thromboplastin. Gradually evidence has been accumulated that the deficient factor in hemophilia resides in the plasma rather than in the platelets as formerly thought. Fundamentally it is shown that the defective hemostasis of hemophilia is due to a lack of available thromboplastin in the blood. The prothrombin is normal both qualitatively and quantitatively but because of the lack of thromboplastin in hemophilic blood, little prothrombin becomes converted into thrombin. This is shown to be a fact as little prothrombin is consumed in the coagulation of hemophilic blood. It is emphasized that the de-

termination of the consumption of prothrombin offers the first promising means for assaying the thromboplastic activity of the blood. Normal plasma contains enough available thromboplastin to convert from 80 to 90 per cent of the prothrombin to thrombin. By giving a hemophilic patient a plasma transfusion enough thromboplastin can be supplied to maintain effective hemostasis for 24 to 48 hours.

The coagulation time is of limited value as a measure of hemostatic effectiveness particularly as a guide to the prothrombin level. In the case of hemophilia the coagulation time is a somewhat better guide but unfortunately even in this condition a temporary reduction of the clotting time to normal does not necessarily assure good hemostasis.

The results obtained in the present investigation clearly show that the platelets are essential for coagulation since they appear to be required for the activation of the thromboplastin which is present in the plasma in an inactive form. It appears that on disintegration the platelets liberate an enzyme which acts specifically on the precursor of thromboplastin, thromboplastinogen. Hemophilic platelets would thus be normal in function but have no thromboplastinogen to convert. As soon as this material is supplied by the transfusion of normal plasma, the hemophilic platelets react and daily normal coagulation is established.

The agglutination and disintegration of platelets appear to be contingent upon the formation of thrombin. In hemophilic blood in which the production of thrombin is minute, the platelets remain unaltered. This suggests that the production of thrombin is related to platelet disintegration and it may well be that the following chain reaction is set up: formation of thrombin brings about the disintegration of platelets, which in turn makes more thromboplastin available to form more thrombin. The coagulation of normal blood which is characterized by a latent period followed by rapid conversion of fibrinogen to fibrin strongly suggests such a chain reaction.

LEROY J. KLEINWASER, M.D.

Denatured Calf Plasma for Transfusion. J. MILKA, V. RAPANT and B. ZAPLETAL. *Lancet* Lond., 1947 3 382.

To replace human plasma for transfusion calf plasma must have its antigens removed. Such plasma without its antigens is called denatured calf plasma (D.C.P.) by the authors. To remove the antigens the calf plasma is treated with formal and heat. A change in the appearance of the calf plasma during this process (it becomes opalescent when viewed against a dark background) is important in the proof that the plasma has been denatured. The denatured calf plasma is then refrigerated in sterile containers, and it lasts almost indefinitely.

The author's laboratory research proved the following facts:

1. Denatured calf plasma does not contain agglutinins for human blood corpuscles of groups A, B or AB.

2. It never hemolyzes human red corpuscles.
3. It does not produce precipitates against the proteins of denatured calf plasma or of natural calf serum in guinea pigs, rabbits, or in the human being.

4. With denatured calf plasma we cannot sensitize guinea pigs so as to produce anaphylactic shock after the injection of calf serum or denatured calf plasma. The authors confirmed Masson's work as to the harmlessness of infusions of denatured calf plasma.

Blood and plasma are more valuable than saline infusions in combating shock because of their colloid osmotic proportion. The authors demonstrated that the denaturing process does not reduce the colloid osmotic pressure of the denatured calf plasma proteins. They also showed that denatured calf plasma is not excreted in the urine even after repeated administrations.

The authors believe that the incidence of intolerance in blood transfusions, which intolerance occurs despite every precaution, can be reduced by the use of denatured calf plasma. However the chief advantage of denatured calf plasma is its easy availability and low cost. Transfusions of this substance are recommended whenever there is a shortage of blood donors and whenever it is preferable to give plasma instead of whole blood.

MISCELLANEOUS

The Origin and the Physiology of Heparin; The Specific Therapy in Thrombosis. J. ERIC JORPES. *Ann. Int. M.* 947 7 36

Heparin is a mucopolysaccharide resembling the chondroitin sulfuric acid of cartilage. The strongest samples contain 36 per cent of a uronic acid and about 23 per cent of glucosamine. These components make up 90 per cent of the organic structure of heparin. Heparin contains ester sulfuric acid not only one group to each disaccharide unit but three groups, which make up not less than 45 per cent of the weight of the free acid. The uronic acid in heparin is claimed to be glucuronic acid. It is unknown whether heparin contains an acetyl group. There is no free NH_2 group. Acetic acid cannot be obtained from heparin except in much smaller quantities than would be calculated. The amount obtained by ordinary methods might come from impurities. It is unknown whether heparin is a definite chemical compound or whether it is a mixture of disulfuric and trisulfuric acid esters of one and the same polysaccharide, having a composition similar to that of Karl Meyer's hyaluronic acid. All types of polysaccharides acquire anticoagulant properties if thoroughly esterified with sulfuric acid. Heparin has a high molecular weight and carries an exceptionally strong negative charge. The high content of ester sulfuric acid is the outstanding feature in its structure. The anticoagulant activity is probably exerted through the electric charges of the high molecular polysaccharide.

Heparin acts on the components of the coagulation system—on the thrombin prothrombin and the

thrombokinase. It neutralizes the serum complex interfering with the Wassermann reaction. In higher concentration it influences the sedimentation rate through the plasma proteins. Its multiplicity of action is probably an expression of the effect of the acidic polysaccharide on different proteins. The interaction of heparin and thrombin is easily reversible. Protamine instantly abolishes the heparin effect by neutralizing its negative electric charge. Protamine sulfate from 50 to 100 mgm., can be injected intravenously in man in 1 per cent solution and brings the coagulation time instantaneously down to normal. Various animal heparins with the same content of ester sulfuric acid have various anticoagulant strengths—a fact difficult to explain. In spite of a strong ionic dissociation heparin exerts an extremely low osmotic pressure in aqueous solution. This is a protective mechanism whereby heparin-producing cells are protected from disruption by water flowing to establish osmotic equilibrium. This also makes heparin useful in blood analysis because it does not cause red corpuscles to shrink.

Heparin gives an extraordinary strong purple violet stain with certain blue basic dyes. One of these is toluidine blue which stains only high molecular esters of sulfuric acid a purple violet. The mast cells stain in this way with toluidine blue. They have a characteristic perivascular position. They are able thus to void their granular contents almost directly into the blood stream. They follow the capillaries and are thus rich in inflammatory tissue. Among the victims of Hiroshima, who showed a general bleeding tendency, there was a general increase in the mast cells in their tissues. Hyperheparinemia has been produced with an increase in mast cells by irradiation in dogs. Urticaria pigmentosa with multiple petechiae in the skin is a disease with abnormal accumulations of mast cells in the skin. It is now known that the mast cells produce heparin.

Heparin is clinically used in cases of thrombosis to influence the coagulation time. It can be used postoperatively to prevent thrombosis and embolism. Prophylactic use of anticoagulants is made difficult by their expense and by the tendency of patients to bleed from their operative site. However they should be used postoperatively or after childbirth when there is a previous history of thrombosis. The author cites data showing that heparin shortens the course of thrombosis of the leg and decreases the incidence of later complications, such as edema. Heparin effects need not be checked by blood analysis except in special cases—as in elderly people with impaired renal function. Heparin and dicumarol often have quite a specific effect in protracted non-viral pneumonias which are resistant to antibiotics. Latent pelvic thrombosis producing pulmonary emboli is more common in these cases than is suspected. Anticoagulants will be useful in preventing clotting in the capillaries in various diseases. The author cites a case wherein heparin cleared up an anuria following a transfusion of incompatible blood.

JAMES WEAVER, M.D.

The Use of Dicumarol as an Anticoagulant; Experience in 2,397 Cases. EDGAR V ALLEN, EDGAR A. HINES, JR., WALTER F KYALL, and NELSON W BARKER. *Ann. Int. M.* 1947 27 371

The expert use of the anticoagulants heparin and dicumarol has improved tremendously the outlook for patients who have acute vascular thrombosis.

An over-all consideration of 1513 postoperative patients treated with anticoagulants indicates that the following results were achieved

Eighty-five patients survived who would have been expected to die from pulmonary embolism 250 patients were spared venous thrombosis or nonfatal pulmonary embolism. In 506 additional postoperative cases in which dicumarol was used prophylactically venous thrombosis occurred in but 2 instances there was no pulmonary embolism.

A consideration of 208 medical patients indicates that fatal pulmonary embolism was prevented by anticoagulants. Nonfatal pulmonary embolism and venous thrombosis occurred very infrequently. A study of 50 cases of acute myocardial infarction in

dicates substantial reduction in the incidence of further myocardial infarction and in arterial embolism and venous thrombosis. Survival of the extremity occurs in 91 per cent of cases of arterial embolism and in 81 per cent of cases of arterial thrombosis if treatment with anticoagulants is begun early and supplemented by other treatment.

Our experiences indicate clearly that the anticoagulants are effective in the treatment and prevention of vascular thrombosis of medical patients just as they are effective in the care of postoperative patients with these conditions. Fatal pulmonary embolism can be prevented and venous and arterial thrombosis can be halted in most instances. Early treatment of sudden arterial occlusion with anticoagulants and other measures results in survival of the extremity in 90 per cent of instances of embolism and 80 per cent of instances of thrombosis.

In general the use of anticoagulants constitutes the greatest contribution to the successful treatment and prevention of intravascular thrombosis and embolism.

SURGICAL TECHNIQUE

OPERATIVE SUROERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Intravenous Oxygen and Pulmonary Embolism.

JACK H. SANDERS and LEONORE M. JONES. *Ann Surg* 947 136 208.

Because of the controversial state of reports in the literature on intravenous oxygen administration for the treatment of shock, the authors have made a study of the effects of the administration of intravenous oxygen on 2 patients in shock and on 4 patients who were observed to be in a fairly stable cardiorespiratory condition. One experiment was done with the use of 50 c.c. of venous blood drawn from a dog and by noting the oxygen saturation produced in vitro. Studies showed that after the passage of oxygen bubbles through venous blood at rates comparable to intravenous administration, the blood failed to show any appreciable absorption. The authors concluded that gas bubbles coalesce in the veins become of considerable diameter by the time they reach the pulmonary arteries and may occlude the smaller arteries. The resulting gaseous embolism causes a decreased pulmonary circulation arterial hypoxemia and systemic hypoxia, and these effects probably are intensified by reflex pulmonary spasm and bronchospasm. The authors state also that the present status of intravenous oxygen as a therapeutic measure is doubtful and because of the possibility of pulmonary embolism, is hazardous. It is thought that some of the ill effects of pulmonary gaseous embolism might be alleviated by the administration of atropine and papaverine before intravenous oxygen is given. A state of shock or of anesthesia may also diminish these reflexes.

W. FOSTER MONTGOMERY, M.D.

Clinical Evaluation of Bovine Serum Albumin as a Blood Substituta. DAVID STATE, FELIPE TORRES ROMERO, MANUEL MORENO CASTELLANOS, and OWEN H. WANGENSTEEN. *Surgery* 947 1 424.

The authors made use of highly purified bovine serum albumin fractions obtained by the precipitation of bovine plasma by ethanol alcohol at 5 C. Four hundred and sixty-nine injections were made into 410 patients with 12 (2.9 per cent) immediate reactions and 38 (9.2 per cent) delayed reactions. There was therefore a marked reduction in the incidence of immediate and delayed reactions attending the use of purified bovine serum albumin fractions.

The immediate reactions were of 2 types (1) The anaphylactoid, which was characterized by dyspnea, cyanosis, and fall in the blood pressure, and (2) the pyrogenic, characterized by chills and fever. In the main, the reactions were moderately severe. The onset of the delayed reactions was usually from 12 to 4 days after the injection and was characterized by ticaria, erythema, myalgia, arthralgia, and fever.

In the severe cases, there were petechiae and ecchymoses. The incidence of both immediate and delayed reactions was no greater in patients who received multiple injections than in those who received a single injection.

Procalcine given intravenously (1 gm. in 100 c.c. of saline solution over an interval of one hour) is a very effective agent in the treatment of delayed serum sickness. In concentrated solutions (15 per cent), bovine serum albumin would appear to be an effective agent in the prevention and treatment of shock. For a large blood loss (in excess of 80 c.c.) blood obviously would be a more satisfactory agent with which to combat shock. Because of the persistence of and incapacity caused by the delayed reaction, crystallized bovine serum albumin is not recommended at present as an ideal blood substitute.

C. FRED GORDON, M.D.

Changes in Plasma Volume and Mean Arterial Pressure after the Intravenous Injection of Concentrated Human Serum Albumin in 21 Patients with Oligemia and Hypotension. ALICE LOWELL, ANNE COUDREMAN, and DUDMAN W. RICHARDS, Jr. *Surgery* 1947 221 442.

The authors have studied the intravenous use of concentrated human serum albumin to determine the efficacy of this agent in assisting the recovery from shock and shocklike conditions. The present article is concerned primarily with a comparison of the effects upon mean arterial blood pressure and plasma volume of the intravenous injection of concentrated human albumin solutions when given with or without additional intravenous fluids.

It was determined that the intravenous administration of concentrated albumin solution with or without additional fluid, was free from untoward clinical reactions as evidenced in two groups of patients (18 in one group and 30 in the other) one receiving concentrated albumin without, and the other receiving concomitant solution with, additional fluid. The injection of concentrated human solution alone (without concomitant saline solution) was associated with an immediate increase in plasma volume of about 15 c.c. per each gram of albumin injected and retained, and a fall in the hematocrit. Since the expected in vitro value is 18 c.c. per gram of albumin, it appears that the albumin retained did not hold a volume of fluid commensurate with its theoretic osmotic activity. However the intravenous injection of 400 c.c. of isotonic saline solution along with the albumin resulted in a somewhat greater increase in plasma volume per gram of albumin both injected and retained the average being 16 c.c. which compares more favorably with the theoretic value of 18 c.c.

Patients in severe shock, presumably with continuing blood or plasma loss (burn or peritonitis)

showed much smaller increases in plasma volume per gram of albumin given and retained namely an 8 c.c. average in shock against a 14 c.c. average in nonshock patients.

The administration of 100 c.c. of concentrated albumin (25 per cent) without additional fluid corresponds to about 200 c.c. of plasma.

In 25 per cent of the cases studied the total circulating protein after the injection of albumin was significantly greater than expected. This increase suggests the possibility that during recovery protein may be mobilized from body reserves or that blood in static pools during the hypotensive period may be returned to the circulating blood as the general circulation improves.

There was noted a rise in intra-arterial blood pressure (average 17 mm. of Hg.) in both groups of patients but the blood pressure failed to reach accepted normal levels. Hemodilution with its decrease in blood viscosity may account, at least in part, for the failure of the blood pressure to rise to accepted normal levels. A stationary or falling blood pressure with a rapid increase in plasma volume after the intravenous injection of albumin may indicate failure in vasomotor tone. ROBERT TURELL, M.D.

The Use of a Mixture of Pure Amino Acids in Surgical Nutrition SIDNEY C. WERNER, *Ann. Surg.*, 1947 126 169.

A careful clinical study was made with a metabolism ward set up at the Presbyterian Hospital, in New York. The authors concluded that the healthy adult remains in nitrogen equilibrium except for minor daily fluctuations. Their data indicates that no excesses of nitrogen appear in the urine when nitrogen is withheld postoperatively and that the nitrogen excretion may be less than that of an injured patient on the same intake. High carbohydrate regimens spare nitrogen, which would be unlikely if the nitrogen loss were the result of toxic destruction of tissues, as suggested by others. It was thought that there was no increased rate of catabolism or tissue destruction in the absence of nitrogen intake. Contrary to the anabolism theory the authors believe that the incoming nitrogen is not entirely wasted and a high nitrogen intake lessens or reverses negative nitrogen balance after trauma. The authors assume that there is an increase in the rate of both anabolism and catabolism.

The use of protein hydrolyzates for parenteral nutrition has been shown to have certain practical difficulties. A satisfactory protein substitute is still desirable and a mixture of pure amino acids, "VUJ" was given clinical trial. This mixture of pure amino acids in 10 per cent and 8 per cent solution was used clinically. Seventy three patients received the 8 per cent solution which seemed the more satisfactory. Few toxic effects were noted with the 8 per cent solution. In the series, only 1 death of obscure origin was reported. It was feasible to give up to 1,500 c.c. of the amino acid solution twice daily to provide 28.8 gm. of nitrogen.

For evidence of increased catabolism if nitrogen has not been given after the injury the authors include three conditions which are necessarily present in addition to injury, namely, the presence of incoming nitrogen inanition and severity of injury.

Twenty patients with peptic ulcer and 1 patient with lymphoma of the stomach were submitted to partial gastric resection and given the pure amino acid preparation during the postoperative period. A similar series of 29 cases served as controls. A fifth of the controls appeared to do less well than the amino acid treated patients. It was pointed out that the results in the two groups were similar enough to suggest that possibly unconsidered postoperative therapy with amino acids may be unnecessary. Clinical benefit criteria were tabulated. Complications and the length of hospital stay were thought lessened with the administration of amino acids. The return to normal temperature after operation appeared sooner. Abdominal distention and postoperative edema of the stoma showed a higher incidence without treatment. The treated patients appeared to be stronger than the controls. Appetite and ability to eat a bland diet may have been improved with amino acid therapy.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Frostbite. KURT LANGE, DAVID WEINER, and LYNN J. BOYD *N. England J. Med.*, 1947 237 383.

The physiology of frostbite is characterized by blanching followed by a pinkish discoloration of the involved part. The thawing phase further intensifies the discoloration, to which is added swelling and temperature elevation. During this period blister formation is pronounced and is rapidly followed by vesicle rupture. If the blister fails to rupture it forms a dense gelatinous adherent mass on a red inflammatory base. Sensation to pin prick, heat, and cold is lost. Within a period of 3 to 10 days well demarcated areas of gangrene appear. The intravenous injection of fluorescein during the acute phase of frostbite in the experimental animal is characterized by a total absence of fluorescence. During the thawing period hyperfluorescence is marked because of the increased blood flow and capillary permeability. This is followed again by another phase, 48 to 140 hours after cooling during which the part is completely nonfluorescent as a result of vascular occlusion and the onset of gangrene. Microscopy of the capillaries reveals the clumping of circulating red cells as the basic phenomenon of vascular occlusion. During the thawing period the cell masses break up and the red cells resume their independence. When this fails to occur the agglutinative thrombi of red cells may undergo complete hyalinization after from 3 to 8 days. The escape of plasma protein into the interstitial spaces is followed by fibrinization of the clot with subsequent fibrosis and collagen formation described as lardaceous inflammation.

Animals subjected to cooling experiments and heparinization failed to develop gangrene, whereas all the animals in the control group developed gangrene under similar conditions. Of great significance in the former group was the absence of agglutinative thrombi and hence the inhibition of gangrene by heparinization. A series of similar experiments were made on human volunteers.

The following tests were made the effect of topical freezing, freezing with immediate heparinization, heparinization delayed for 24 hours after freezing, interim cooling and interim warming combined with heparinization. Untreated freezing caused gangrene. Immediate and early heparinization gave the best therapeutic results, the hilster fluid did not clot and fibrosis did not develop. Interim cooling and warming created a more intense type of gangrene than that caused by freezing alone. Recommended for the treatment of frostbite is the intravenous administration of a total of 300 mgm. of heparin in 2,000 c.c. of normal saline for a 24 hour period delivered at the rate of 20 to 25 drops per minute. Heparin in Pitkin's menstruum is not recommended because of pain associated with its injection. Clotting time is checked by the Lee and White method at 12 hour intervals with blood coagulation maintained between 30 to 60 minutes. Treatment should be maintained for 6 to 7 days. Resulting surgery is limited and conservative.

BENJAMIN G. P. SHAPIROFF, M.D.

Grafts of Skin and Cartilage. JAMES BARKETT BROWN, BRADYDOR CAMPOS, CARL E. LISCHKE, and W. BOWDOEN DAVIS. *J. Am. M. Ass.* 947:134, 95.

Composite free grafts from the ear comprising two surfaces of skin with cartilage between have proved increasingly useful in the replacement of tissue lost from the nasal tip, nostril borders, and columella. The use of free transplant has made it possible to perform repairs in a single procedure with minimal deformity to the ear and has eliminated the need of multiple procedures in moving distant flaps.

The length of the graft is not limited but it is doubtful whether grafts over 1 cm. in width can be successfully transplanted. The columella, tip and one ala of the nose can be restored with a single graft. To correct a short ala, the alar scar can be opened and a wedge-shaped graft inserted or a constricted nostril due to a burn can be opened by excision of the scar and repaired with a composite graft. Adequate minute blood supply with as much well vascularized surface as possible available for contact between the nose and the graft is necessary in preparation of the defect for the graft.

A pattern of the final defect is helpful in selecting a suitable part of the ear for the donor area and accurate measurement of the graft.

Portions of the normal ear with thin skin over the cartilage are best. If a long or wide graft is necessary the rim of the helix is the only possible source. Separation of cartilage from skin should be avoided. Repair of the ear in large excisions requires a scalp

flap in which the open ear is buried. Smaller excisions can be repaired by direct closure or by local flap and graft.

The graft is accurately sewed in place. In dressing, adequate immobilization is secured by padding the nostrils and applying gentle but firm external pressure.

LOUIS T. BIRAR, M.D.

Acute Subpectoral Abscess: A Surgical Emergency. KNOWLES B. LAWRENCE and THOMAS J. ANDERSON. *N. England J. M.* 1947:37:390.

Expectant treatment and delay in the surgical treatment of subpectoral abscess may lead to extensive tissue destruction and axillary abscess. More serious complications such as subscapular space infection, empyema, mediastinitis, and septicemia may develop. Sulfonamide therapy and other antibiotics are only delaying in action, whereas early surgical drainage is essential in all cases.

Subpectoral abscess is characterized by a ribbed infection of the upper extremity leading to suppurative infection of the infraclavicular lymph nodes located along the subclavian and axillary vessels lateral to the anterior scalenus muscle. Suppuration may extend through the axillary fascia, the fascia of the axillary space, or may follow the vascular pathways to the arm or mediastinum. Relatively high pressures may develop in the subpectoral space before rupture occurs into the surrounding fascial spaces. Edema of the overlying muscles contributes to the swelling of the area and the severity of the pain. The primary focus is frequently an insignificant infective lesion of the middle finger, a lesion on the chest wall, or in the shoulder area.

Clinical manifestations consist of pain in the shoulder area that progresses in intensity and motion becomes limited and painful. If the infecting organism is the streptococcus the patient is usually ill and toxic. Tenderness and swelling is present in the subpectoral region, the shoulder, the axilla, and the supraclavicular fossa. Signs of fluctuation cannot be elicited until late, when the suppurative process has ruptured through the axillary fascia. Differential diagnosis involves the shoulder joint and its bursae.

Treatment should be directed at early incision and drainage of the subpectoral space even in the absence of frank suppuration. The incision should be made in the axillary fascia at its line of fusion with the lateral margin of the pectoralis major muscle. The skin incision is made at right angles to the anterior axillary fold. After exposure the forefinger is used for blunt dissection high up into the space as far as the anterior scalenus muscle and the axillary structures. Counter incisions may be made to secure dependent drainage.

BENJAMIN G. P. SHAPIROFF, M.D.

Streptomycin Therapy in 52 Cases of Bacterial Infection. LEWIS W. KANE and GEORGE E. FORT. *N. England J. M.* 947:337-33.

The authors report 52 cases of bacterial infection treated with streptomycin. Urinary infections, b-

cluding 38 cases of pyelonephritis and 1 case of cystitis, made up the bulk of the cases. All of the infections were due to the gram negative bacilli and were treated with intramuscular streptomycin given on a 4 hour schedule. The total daily dose ranged from 0.5 to 2 gm. and was continued for 3 days after the urine became sterile. Most important, because of the fact that streptomycin is most effective in an alkaline medium the urine was alkalinized in the majority of the cases. One teaspoonful of a 50 per cent solution of sodium citrate 3 times a day was usually sufficient. In the presence of pulmonary or peripheral edema potassium salts were substituted for sodium citrate. Thirty of the 40 patients with urinary infection had sterile urine for 1 week after therapy was discontinued and were considered to be cured. Only one questionable relapse was found in this group. Moderate structural damage, such as dilated calyces, slight hydronephrosis, partial stricture of a ureter or small nonobstructing calculi did not seem to preclude a cure if the infecting organism was sensitive. The authors attribute their better results as compared to those reported by other workers to the alkalization of the urine.

In addition 3 patients with nonspecific urethritis were given streptomycin therapy with good results. Four patients with Haemophilus influenzae infections were likewise treated with excellent results. In the 2 cases of Haemophilus influenzae meningitis from 0.05 to 0.1 gm. of streptomycin was given intrathecally. Three patients with bronchiectasis were treated with streptomycin and penicillin aerosol but only 1 patient was thought to have been benefited. A case of lung abscess due to Haemophilus influenzae showed marked improvement under this therapy and recovery of a patient with Pseudomonas aeruginosa septicemia was effected.

F J LIEKMANN JR. M.D.

Polymyxin: A New Chemotherapeutic Agent P G STANLEY, R G SHEPHERD and H J WHITE. *Bull Johns Hopkins Hosp* 1947 81: 43

Polymyxin is a new antibiotic substance derived from the *Bacillus polymyxa*. Its potency is assayed as that unit of activity which is equivalent to the amount of polymyxin per milliliter which just inhibits the growth of *Escherichia coli* MacLeod strain. Polymyxin is a white, water soluble powder with a pH of 5 in aqueous solution. It is relatively stable in dilute acid alcohol solutions and to heat. Also, it is not affected by prolonged incubation with pepsin, trypsin or pancreatin.

In vitro by the agar streak method from 0.5 to 16 micrograms of polymyxin per milliliter inhibit 56 of 64 strains of gram negative bacteria. This antibiotic is particularly effective against virulent strains of *Klebsiella pneumoniae* or *Pasteurella multocida*. A single dose of 10 micrograms per 20 gram mouse is sufficient to protect practically all the inoculated mice against the *Klebsiella pneumoniae*. Chickens injected with a fatal strain of fowl typhoid can be protected by the daily injection of an average

of 16 mgm. of polymyxin per kilogram of body weight.

Polymyxin is effective subcutaneously and intravenously. For oral potency the drug must be increased to 64 times the parenteral dose. The formaldehyde bisulfite derivative of polymyxin causes no local irritation, even when injected in 15 per cent solution. It is not toxic, even when injected in 100 milligram doses for a period of 30 days.

BENJAMIN G P SHANTOFF M.D.

ANESTHESIA

Skin Temperature as a Clinical Aid during Anesthesia J CLUTTON-BROCK. *Proc R Soc Med Lond* 1947 40: 607

Skin temperature readings are used to distinguish between falls in the blood pressure which are due to shock and those which are due to other causes of little significance. The combined fall of skin temperature and blood pressure readings predict the patient's need for resuscitation.

A mercury in glass thermometer is used which reads from 80 to 170° F. The ring bulb is attached by elastoplast to the patient's forehead and changes in temperature rather than absolute readings are considered to be of significance. After an initial rise during the induction of the anesthesia, the temperature of the skin will remain steady unless shock occurs. A fall of 3 degrees or more is believed to show a considerable degree of shock. A marked fall in blood pressure can occur without a fall in skin temperature when the low blood pressure is due to any cause producing sluggishness of the circulation without true shock, such as a high spinal anesthesia or changes in position of the patient. The author has never found any harm to come to a patient when the blood pressure fell without a concomitant fall in the skin temperature. When however the blood pressure and skin temperature fall together the patient needs energetic resuscitation.

EDITH EASON M.D.

Intravenous Procaine: A Preliminary Report DAVID J GRAUBARD, RAFAEL W ROBERTZ and MILTON C PETERSON. *N York State J Med* 1947 47: 3187

This report deals with the intravenous use of procaine hydrochloride for the control of pain in traumatic and inflammatory conditions. There were no serious ill effects in 140 cases with 608 infusions.

The physiology and pathology of inflammation and the pharmacology of procaine are reviewed. The authors believe that in traumatized or inflamed areas procaine administered by the intravenous route has a twofold action: (1) direct action on the irritated nerve fibers, and (2) indirect action of the diethyl aminoethanol on the endothelium of the blood vessels.

To simplify the work, the term procaine unit was devised. This is the amount of procaine calculated at 4 mgm. per kgm. of body weight to be given

in 20 minutes in a 0.5 per cent isotonic saline solution. For accurately determining the dosage and for a constant uniform rate of administration a flowmeter was utilized.

Typical signs and symptoms as observed during the administration consist of a sensation of warmth throughout the body a flush over the head, face and neck, dryness of the mouth dilatation of the pupils and lightheadedness. Many patients feel comfortably relaxed with the alleviation of pain. The authors strive not to exceed these manifestations during the administration of procaine. They have noted no cases of procaine sensitivity or any contraindications to the use of this drug.

The results in the management of pain in trauma have been uniformly good, except for the cases of herniated intervertebral disk. The inflammatory cases on the whole responded well. In the miscellaneous cases, the results were relief of spasm increased mobility and improved muscular control.

It was concluded that

1. Intravenous procaine infusion for the management of pain in trauma and inflammatory conditions is a safe hospital procedure, provided that the administration is controlled.

2. The indiscriminate and careless intravenous administration of procaine may prove dangerous.

3. Intravenous administration of procaine should be considered as an adjunct to the management and treatment of selected traumatic, inflammatory and spastic conditions.

MARY FRANCES POT, M.D.

Pseudomonas Pyocyanea Meningitis following Spinal Anesthesia IAN M. DAVENPORT *Lancet*, Lond., 1947 1: 653.

The author points out that the conscientious recording of cases of meningitis following spinal anesthesia is important in order to emphasize the possible dangers of the method.

In one day the repair of 3 hernias was carried out under spinal anesthesia. The first patient made an uninterrupted recovery. In the 2 others *Pseudomonas pyocyanea* meningitis developed. One of these patients recovered after treatment with sulphamerazine, the second died.

An exhaustive attempt to trace the source of the infection in these cases was without success. In a similar case not reported here, the source was so-called sterile water in the operating theater.

Emphasis is laid on the importance of a rigid technique of asepsis in lumbar puncture whether for diagnostic or anesthetic purposes.

MARY FRANCES POT, M.D.

Discussion on Anesthesia for Cesarean Section RUFUS C. THOMAS, J. H. PEEK, C. MCINTOSH, MAX SMALL, KATHERINE LLOYD-WILLIAMS, and Others. *Proc. R. Soc. M. Lond.* 1947 40: 557.

THOMAS. The essential criteria for any anesthetic for a cesarean section must be safety for the mother and child and, subject to this, ease of operating for the surgeon. The discussant has used heavy nuper-

caline for many cesarean sections during the past 5 years. The arguments against spinal anesthesia for the pregnant woman are (1) it should not be used in patients with severe anemia and low blood pressure, (2) a number of cases of meningitis, some of them fatal, have followed spinal anesthesia, and (3) post-operative headache is not an infrequent occurrence.

Some advantages of spinal anesthesia with heavy nuper-caline include (1) it is relatively painless, (2) the anesthetic has no effect whatever on the baby, and (3) the surgeon has maximum relaxation for the operative procedure. The technique should be strictly and rigidly aseptic. The amount of heavy nuper-caline used is 2 c.c. given between the third and fourth lumbar vertebrae. This series includes 346 cesarean sections under heavy nuper-caline anesthesia. There were no deaths. The infant mortality rate was 3.4 per cent; 2 were stillborn, and 10 died.

PEEK. A brief résumé of 51 cesarean sections done under continuous caudal is given. There was no maternal mortality and no higher incidence of morbidity than is experienced in any series of cesarean sections. The advantages of continuous caudal anesthesia are enumerated.

MARSHALL. There are several reasons why inhalation anesthesia is unsatisfactory and dangerous for cesarean section. Accidents may occur during induction because of the light anesthesia with little if any preoperative medication which will cause vomiting and aspiration of the stomach contents into the bronchial tree. Furthermore, most of the inhalation anesthetics induce some degree of anoxia.

The only justifiable choice lies between spinal and local anesthesia when certain complications of labor have occurred. Spinal anesthesia is without effect on the fetus. Interest is increasing in local anesthesia for cesarean section, although it is not likely that many obstetricians will ever extend it to the majority of their patients. The discussant makes a plea that local anesthesia should be considered for the poor-risk patient. One word of warning is given to the effect that with an uncorrected transverse position the lower uterine segment should never be opened under local anesthesia alone. If the back or the shoulder and arm fall into the wound, extraction may be almost impossible.

LLOYD-WILLIAMS. The discussant gives an account of her wide experiences with anesthesia for cesarean section which dates from 1928 to the present time. Having tried most all forms of anesthesia she now prefers pentothal with gas and oxygen, adding trilete vinyl, or ethyl ether in minimal amounts. She does not recommend spinal anesthesia although it was used in 85 of her series of 304 cases.

DAWKINS. In this author's series of cases epidural anesthesia has given the most satisfactory results. The technique of this block is as follows:

A skin wheal is made between the second and third lumbar vertebrae and a Howard Jones spinal needle inserted in the midline. Odum's glass indicator containing an air bubble is attached and the needle is very slowly advanced into the ligamentum flavum.

until the air bubble is sucked in toward the patient by the negative pressure in the epidural space. Forty five cubic centimeters of 1-600 nupercaine in 0.45 per cent normal saline solution are used. Ten cubic centimeters are given slowly as a test dose, after it is certain that no cerebrospinal fluid can be withdrawn. After an interval of 5 minutes a further 35 c.c. of nupercaine are injected slowly (again with aspiration several times). The needle is then removed and the patient lies on her back in a slight foot-down tilt. It usually takes 25 minutes for the analgesia to be complete. In the discussant's experience all the babies breathed spontaneously at birth and there were no headaches, chest complications, or urinary problems. Vomiting was almost negligible.

CAVE. Under spinal anesthesia the surgeon can proceed with cesarean section at whatever pace he likes, safe in the knowledge that the fetus is not being affected. Furthermore the muscular relaxation will be good and there will be minimum risk of postpartum hemorrhage.

SMITH. This discussant has had wide experience with local anesthesia for cesarean section and finds it the anesthetic of choice. EDITH EASON, M.D.

Curare: Its Past and Present. STUART C. CULLEN
Anesthesiology 1947 8 479

This is a review of the history of curare and an investigation of the development of the preparations in clinical use today. Much is learned of the witch craft and daily lives of the South American Indians and the exploits of the early explorers. It is also evident that although we are able to apply the drug satisfactorily in clinical practice we have probably not extended the scope of its usefulness over that which has been proposed by the clinicians of the nineteenth century.

Clinical application was first attempted in 1866 by 2 French physicians who tried to allay and prevent the convulsions of epilepsy. Current enthusiasm for the clinical application of curare is largely due to the efforts of A. E. Bennett who popularized the use of curare in the control of convulsions associated with metrazol or electric shock therapy.

Bennett's exhibit at the 1940 meeting of the American Medical Association prompted several anesthesiologists to consider the possibility of using curare as a means of improving muscular relaxation during inhalation anesthesia. The rational and safe utilization of curare in anesthesiologic practice was

defined by the anesthesiologists who were among the first to employ curare in volume. These fundamental principles emphasized that curare was to be used only as a means of providing muscular relaxation and that some anesthetic or analgesic agent must be administered to provide pain relief. It was emphasized that the drug was selective in action and graded doses were recommended as being capable of producing the desired relaxation without interfering with the respiratory efficiency. It was emphasized that the principal advantage of curare in anesthesiology is to provide muscular relaxation and permit the anesthesiologist to effect anesthesia with low concentrations of potent anesthetic agents. It is also possible to extend the usefulness of impotent agents.

The laboratory investigations that accompanied the introduction of curare into anesthesiologic practice established the principle that the dose of curare is influenced by the anesthetic agent because some of the anesthetic agents have curariform properties of their own. Other research indicated that curare in therapeutic doses is capable of lowering the blood pressure in a few patients. It was determined further that curare does not alter cardiac rhythm nor does it interfere with certain elements of tissue metabolism, but it does cause relaxation of the small intestine. The lack of anesthetic or soporific properties of curare has been pointed out.

To date there has been a minimum number of disadvantages and dangers accompanying the rational use of curare. It is obvious that means for providing prompt and efficient artificial respiration must be at hand when curare is administered. The indiscriminate employment of prostigmine to overcome the effects of the improper use of curare should be discouraged. The bronchospasm may be relieved by the administration of additional curare. In spite of laboratory and considerable clinical evidence that curare has little or no influence on the heart and peripheral circulation it appears that large doses for long periods may cause a deterioration of the peripheral circulation.

Curare has secured a respectable position in the compendium of therapeutic agents. There is much that curare can do to enhance the knowledge of fundamental physiologic processes. It can be anticipated however that this jungle poison will justify the faith in it that all its ancient and contemporary patrons have had. MARY FRANCES POZ, M.D.

sputum are due to the asbestos needle, and serve as a nucleus surrounded by a gelatinous coating.

The symptoms are dyspnea and irritating cough. In advanced stages there are circulatory disturbances and hypertrophy of the right heart. Bronchopneumonia and bronchiectasis are secondary complications. Tuberculosis does not occur with asbestosis. The prognosis is not good, the average length of life being 15 years, whereas in silicosis it is 40 years. The time interval between exposure to the asbestos dust and development of the asbestosis is from 9 to 10 months.

The diagnosis of asbestosis is made by means of the clinical history and roentgenograms. It is divided into three stages. Stage 1 reveals a fine linear fibrosis in the basilar lung fields (Fig. 1). Stage 2 reveals nodules plus widened hila, but no hazy layering. Stage 3 reveals marked confluent density in the bases and emphysematous apices.

One hundred and twenty-six cases are reported. 94 (75%) were stage 1 with an average mean exposure of 3.4 years. 23 cases (18%) were in stage 2 with an average mean exposure of 7.9 years and 9 cases (7%) were in stage 3 with an average mean exposure of 11.5 years. MAURICE D. SACHS, M.D.

The Roentgenographic Diagnosis of Perforations of the Upper Gastrointestinal Tract into the Mediastinum and Pleural Cavity. GORDON J. CULVER and STANLEY B. CLARK. *Surgery* 1947 23: 458.

Esophageal perforation still carries an extremely high mortality rate. The prognosis depends in part on the location, perforations high in the esophagus having a better prognosis than those lower down. Moerl gave the following reasons for this: (1) a perforation in the cervical portion of the esophagus leads to inflammation in the mediastinum which has a tendency to spread upward where it is more accessible to surgery; (2) any inflammatory process in the upper mediastinum remains more circumscribed than one located lower down; and (3) the site of perforation can easily be reached also with the aid of the esophagoscope. The duration of the underlying pathology prior to the perforation has an additional influence. A long standing process is more apt to lead to a localized periesophagitis than a diffuse mediastinitis because of the time it had to produce a walling off of the inflammation. Perforations of the lower esophagus commonly rupture into the pleural cavity with an invariably fatal outcome.

The perforations occurring higher in the esophagus may be due to foreign bodies, instrumentation or some pre-existing lesion as for example, diverticulum, ulcer or carcinoma. In the lower esophagus because of the weak wall, perforation may result spontaneously under increased pressure from vomiting, retching or coughing.

The authors had the opportunity of observing 4 cases of perforation of the esophagus. Instrumentation was the cause in 2. In the third case there was a pre-existing peptic ulcer of the lower esophagus, and

Fig. 1 (Wegelin) Asbestosis, stage 1. Fine network in the middle and basal fields of the lung picture, already layered with small soft spots. (See p. 304 for abstract.)

in the fourth an ulcer of the cardioesophageal junction. The cases are briefly described and illustrated with their respective roentgenograms. Three of the patients died shortly after the initial symptoms. The fourth patient experienced a perforation high in the esophagus with emphysema of the neck and mediastinitis, and recovered. In the 2 cases with pre-existing ulcers the perforations followed attacks of sudden vomiting, both patients having consumed alcohol prior to the onset of symptoms. Ellason and Welty likewise, described 2 esophageal perforations which resulted from bouts of vomiting and retching after an alcoholic spree.

In 3 of the 4 cases reported by the authors the outstanding clinical manifestation was the resultant hydropneumothorax. In the fourth the perforation was high in the esophagus and there was only mediastinitis present, from which the patient recovered.

The authors believe that a roentgenographic finding of hydropneumothorax associated with the clinical findings of sudden thoracic and/or abdominal pain, shock, and collapse should make one suspicious of perforation of the lower esophagus or stomach into the mediastinum and pleural cavity. A spontaneous pneumothorax is differentiated on the basis of the fact that no pleural effusion is present or if fluid forms, it does not appear until later. A review of the literature shows that most investigators considered the roentgen demonstration of hydropneumothorax, especially in the presence of some pre-existing lesion or a history of swallowing a foreign body or caustic fluid as being diagnostic of esophageal perforation.

Several investigators gave contrast media by mouth in order to visualize the communication between the esophagus and pleural cavity. However, unless the perforation is located in the upper or cervical portion of the esophagus such a procedure is dangerous.

T. LUCOTTA, M.D.

Röntgen Diagnosis in Epiphyseolysis (Coxa Anteverta) MAURICE M. POMERANTZ, *Bull. Hosp. Joint Dis.* N Y 1947 8, 5

The roentgenographic features of epiphyseolysis are reviewed. This condition is of more frequent occurrence and importance than is commonly recognized, and the author had observed approximately 500 cases up to the time of his report. For purposes of roentgenographic description and study he classifies the lesions as follows: (1) slight slipping (2) moderate slipping (3) extreme slipping (4) acute, and (5) chronic (6) long-standing examples.

The earliest distinctive sign of slight slipping when present, is the loss of the "hump" formed by the projecting lip of the epiphysis. After 8 or 9 years of age this normally extends slightly beyond the limits of the superior border of the femoral neck. Occasionally the only sign of the early stage of this condition is merely widening of the epiphyseal plate. On lateral projection there is beginning anteverision of the femoral neck. On anterior posterior roentgenogram, there is a slight increase in the density of the base of the epiphysis which indicates that its position has already been altered by rotation. Under normal conditions in many hips, the epiphyseal plate appears serrated. As the femoral head is detached the serrations disappear and the plate surface of the epiphysis appears as a curved fairly dense line parallel to the margins of the femoral neck. Roentgenographically the epiphyseal line is of increased width there may be noted patchy, confluent, or roughly circular zones near the epiphyseal plate due to irregularities in contour of the epiphyseal surface of the anteverticed neck.

In moderate slipping the condition has advanced so that the capital epiphysis has slipped from one eighth to one-half inch. As the epiphysis is detached it rotates downward so that its widest diameter is nearly in a horizontal plane. It is slightly reduced in height. The head of the femur does not leave the acetabulum—it merely shifts its position within the socket. The epiphysis rotates backward and the anterior lip of the epiphysis migrates inward. As a result of anteverision, the femoral neck appears foreshortened and its upper extremity projects well beyond the limits of the superior pole of the epiphysis.

In extreme slipping there is complete detachment and rotation of the femoral head which, at times, amounts to 90 degrees and the associated extreme anteverision of the neck.

In the acute form of the condition there is usually a history of severe trauma with the associated clinical symptoms of a fracture in the chronic variety there may or may not be a clear history of trauma or one of repeated slight injuries which may not be sufficiently severe to incapacitate the patient. In general, then, any injury may completely separate the femoral head and neck and initiate acute symptoms.

In long-standing examples the condition represents the end results of all stages of the disease in which

the epiphysis is united with the neck and the resultant deformity. FRANK L. HENRY, M.D.

The Value of X Rays in the Study of Postoperative Emergencies and Complications. JAMES T. CUMMINGS, *J. Surg.* 1947 74, 414.

The author presents a series of cases which demonstrate the value of x-ray study in abdominal emergencies and postoperative complications. In the first group of cases are those of intra-abdominal abscess formation.

Case 1 deals with a patient who had recently undergone an operation for drainage of an appendiceal abscess. The clinical findings suggested further abscess formation. A scout film of the abdomen was inconclusive, although absence of gas shadows in the lower left quadrant suggested this as the site of the abscess. A film taken 5 hours following the ingestion of umbratron showed the bowel loops displaced from the lower left quadrant in a manner to definitely indicate an abscess in the lower left quadrant of the abdomen.

Case 2 is a similar one in which the condition followed an appendectomy. Visualization of the colon with an opaque contrast revealed the cecum and ascending colon to be displaced markedly leaving a large vacant space on the outer side of the cecocolon which indicated that an abscess was located in this region.

In case 3 a scout film demonstrated the location of an abscess by the presence of an area which was free of gas shadows and later displacement of a barium filled colon verified it.

In the second group of cases roentgenograms are utilized to demonstrate free air under the diaphragm as its cardinal sign. One group of such cases is represented by rupture of a hollow viscus, such as a duodenal ulcer, an ulcer of the colon, etc.

In case 4 films taken in an upright position reveal a small parallel translucent zone beneath the cupola of each diaphragm which indicates the presence of air due to a ruptured viscus.

A case of subphrenic abscess is that of a woman (case 5) who recently had an operation for a suppurating gall bladder. Roentgenograms revealed elevation of the right diaphragm and some irregularity of the diaphragm in the region of the costophrenic angle. There was no fluid level. In the majority of cases of subphrenic abscess there is no evidence of a fluid level. On fluoroscopic examination fixation of the diaphragm and supraphrenic loop shadows are significant.

Occasionally gas supernatant above the fluid in an abscess is visualized. In case 6 a large gas containing shadow below the right diaphragm indicates the presence of a subphrenic abscess.

In case 7 a lateral position film demonstrates the large right subphrenic abscess. Left subphrenic abscess is considerably less frequent than right.

In case 8 elevation of the left diaphragm, a small pleural effusion, a fluid level with gas above it

below the cupola of the left diaphragm and visualization of the mesial outline of the abscess by contrast material in the stomach demonstrated a left subdiaphragmatic abscess.

In case 9 a film taken with a drainage tube in a subphrenic abscess illustrated perfect drainage in the absence of a fluid level.

In case 10 a bedside roentgenogram revealed a large subphrenic abscess on the right side which was evacuated. After a few days a colon study revealed the tip of an inverted cecum well up under the edge of the liver and opaque material flowing from the cecum into the drainage tract thus demonstrating the cause of the abscess as being that of a ruptured subhepatic appendix.

In case 11 the first x ray film showed flattening and elevation of the cupola of the right diaphragm. On a supine roentgenogram enlargement of the liver was seen. The findings suggested a liver abscess which was not complicated by an aerogenic organism. 300 c.c. of pus were removed by aspiration. In liver abscess of this type fluoroscopic examination from day to day reveals a decrease in the excursion of the diaphragm followed by a final cessation of excursion of the diaphragm on the liver side. Intravenous injection of thorotrast may be used to help visualize a hepatic abscess. X rays are of great aid in biliary tract complications. At the time of surgery the surgeon can introduce some form of opaque material preferably thorotrast into the gall bladder or common duct to determine the patency of the duct or the presence of stones. Before removal of drainage tubes from the common duct its patency is determined by the above method.

In case 12 a nonvisualization of the gall bladder following a recent closure of a gall bladder drainage indicated an obstruction in the cystic duct, which at surgery was found to be an inch long piece of heavy silk. Another group of postoperative cases in which x rays are of value are those in which there are complications following gastroenterostomy, such as simple invagination of one loop or of double loop invagination of a small bowel into the stomach through the gastroenterostomy stoma.

In cases 13 and 15 jejuno gastric invagination was demonstrated on filling the partially resected stomach with barium.

In case 14 a stenosis at the site of the stoma was demonstrated by visualization of dilatation of the duodenum and upper jejunum on x ray examination.

Another group of cases of x ray interest are those of intestinal obstruction. In cases 16 and 17 which were similar the colon was seen to be markedly distended. This was relieved by enema.

Case 18 was one of acute obstruction of the small intestine following operation. In this case characteristic stepladder or parallel arrangement of the coils of small bowel was seen. The coils of small bowel are easily recognized due to the herring bone appearance produced by the valvulae conni-

ventes. Fluid levels in the bowel may be demonstrated by upright or lateral reclining films. A small amount of barium or mbrathor may be used to visualize the small bowel more distinctly but is not considered necessary.

Films of cases 19 and 20 demonstrate the use of umbrathor or barium. Intubation of the small bowel which has become quite popular should be controlled by x ray study. The use of the tube is attended however by a certain danger because of delay.

Preparation of Radioautographs of Thyroid Tumors for Study of High Magnification Truss C Evans. *Radiology* 1947 49 206

In the usual procedure of preparing radioautographs the tissue section mounted on a microscopic slide is placed against a photographic emulsion for a suitable time in the dark. After the proper exposure the two are separated. The photographic image is developed, the microscopic section is stained and a comparative study is made.

A closer contact between the tissue and the photographic emulsion, however, seems desirable. It occurred to the author that the mounting of the tissue section directly on the photographic plate might be advantageous. With this view in mind he elaborated a technique which is similar to that used in preparing histologic slides when paraffin sections are floated onto the microscopic slide. The technique is described in detail.

The present article is limited to radioautographs of thyroid tumors containing radioiodine but the method is applicable to other radioactive substances and other tissues as well. The Eastman median contrast lantern slide plates were found to be the most satisfactory for the autographs. The 2 by 2 inch size is used when the tissue layer is floated on the plate and the 3½ by 4½ inch size when the microscope slide containing the tissue is taped to the plate as in the older method. It is best to produce both types of autographs to obtain a comparative study.

The author cites several cases in which the method has been used to advantage and presents several photomicrographs and autographs prepared by both techniques to prove the point. In the newly described technique proper alignment is automatic and a higher magnification with good detail is possible because the tissue is not removed from the photographic plate. As one changes from low power to high power the plane of the tissue section and of the autograph becomes distinctly separate.

Thus by mounting the tissue directly on the photographic plate one obtains a differential 'staining' of either large or minute regions that have taken up the radioactive iodine. This helps in the study of thyroid function and may aid in determining whether or not a certain case of thyroid neoplasia should be treated with radioactive iodine.

The Metabolism of the Fission Products and the Heaviest Elements. JOE G. HAMILTON. *Radiol.* 97: 947-49, 1955

Fission products getting into the body are dangerous because the quantities which are dangerous are minute compared with those necessary to produce damage by external beta or gamma irradiation. The fission of uranium results in the production of 34 radioactive elements from zinc to europium as well as nearly 200 known isotopes of these 34 elements.

This is a study of the absorption, distribution, retention, and excretion of these radioactive elements. In addition, the behavior of these radioactive elements was observed following their introduction into the body by the 3 major portals of entry: namely, inhalation, oral ingestion, and through cuts and abrasions of the skin. This study is important because very little is known about the metabolism of the radioactive elements involved. The fission products included in this report were strontium, yttrium, zirconium, columbium, ruthenium, tellurium, iodine, xenon, cesium, barium, lanthanum, cerium, praseodymium, and element 61. The studies are being extended to include others of the fission products and eventually it is planned to include them all. Plutonium and the actinide elements (heaviest elements) were also studied.

The method used was to do tracer studies on rats following oral ingestion, inhalation and parenteral

injection of these elements. The absorption, distribution, retention, and excretion of each substance were determined and radioautographic studies were made if there was a high degree of selective absorption to correlate an accumulation of the radioactive elements with the microscopical anatomy.

Only 5 of the fission products included in the study were absorbed to a significant degree from the digestive tract. These were strontium, barium, tellurium, cesium and iodine the latter being absorbed completely. The absorption from the lungs was discussed but the most significant feature appeared to be the metabolic patterns observed following parenteral administration.

There was a surprising predilection to prompt deposition and prolonged retention in the skeleton of many of the long life fission products and the actinide elements. The radioautographs of these elements showed that all of these elements that accumulated in the bone, except strontium, are not deposited in the mineral structure of the bone but rather appear to be localized in and adjacent to the osteoid matrix; thus the radiation was brought in close contact with the radiosensitive bone marrow. It was noted that lanthanum, cerium, praseodymium, element 61, americium and curium have a rather large fraction deposited in the liver. All of the elements except columbium accumulated in bone and were released at a very slow rate.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Homologous Serum Jaundice. I. JAY BRIGHTMAN and ROBERT F. KOFFER. *J. Am. M. Ass.* 1947 135 168.

The ready availability of pooled plasma whether secured through commercial channels, state departments of health or local blood banks has been a boon to medical practice. However, the fact that plasma may carry a virus capable of inducing hepatitis in the recipient has created a new public health problem of major importance.

Follow-up of 649 patients who received transfusions with dried pooled plasma revealed a subsequent incidence of homologous serum jaundice in 4.5 per cent of the patients.

The causative agent appeared to be widely distributed but the rate of attack was variable.

It was significantly higher among persons who were 50 years of age or more. No relation of the attack rate to the amount of plasma administered could be demonstrated.

Investigation of 51 deaths attributed to acute hepatitis revealed 15 cases in which the patients had received transfusion therapy during the 6 months prior to death. Twelve of these had received plasma only.

Twelve deaths attributable to homologous serum jaundice were reported in Upstate New York during a 7 month period.

Plasma, as well as other forms of transfusion therapy should be administered only when the clinical indications are absolute so that the benefits to be derived clearly outweigh the risk of contracting homologous serum jaundice.

Immediate, intensive research toward the elimination of the causative agent is imperative.

HARRY W. FINE, M.D.

Ascariasis as a Surgical Disease (Ein Beitrag zur Askariasis als chirurgische Erkrankung)
NORBERT ZYLKA. *Deut. med. Wochschr.*, 1947 73 417

Shortage of anthelmintic drugs and the extensive use of manure in place of artificial fertilizers are responsible for the great frequency of ascariasis among German children. The author was able to establish the diagnosis of infestation with ascaris in 1 of each 3 children in his institution.

In the course of a year ileus caused by ascaris worms required an operation in 5 patients, 3 children and 2 adults. An ascent of the worms into the biliary ducts was not observed. In several instances the worms evidently reached the stomach because they were found in the vomitus. The third grave complication, namely a penetration of the intestinal wall with subsequent peritonitis was not observed by the author.

In a 34 year old man not less than 1,000 worms produced within the intestines a mass 1 meter long.

All of the patients recovered from the operation which consisted of an enterotomy and removal of the worms.

JOSEPH E. NARAT, M.D.

Two Cases of Primary Suppurative Psoas Myositis.
EMO E. VUORI. *Ann. Chir. Scand.* 1947 96 87

Primary suppurative myositis is a purulent inflammation occurring both in the parenchyma and in the interstitial connective tissue of a muscle and is limited by the muscular fascia. It occurs in patients who present no associated concurrent disease in other parts of the body. Myositis occurs most commonly in one muscle. In the psoas region a primary suppurative myositis is rare but secondary myositis is frequent.

The first case was that of a woman 22 years old. Two months before admission the patient fell on her seat on slippery ice. After some days pain "inside the pelvis" started; it increased daily and caused a limp in the right leg. Walking was easiest in the bent position. Fever began at the same time. The symptoms disappeared almost completely with bed rest and heat although there still was a limp. On admission she had fever, spastic flexion contracture of the right thigh to about 60 degrees, severe pain on attempted extension of the thigh and a palpable tender mass in the iliac fossa. The right psoas shadow did not show on roentgenographic examination. A diagnosis of an abscess of the psoas muscle was made and it was drained operatively. The organism was a staphylococcus. Two days later the temperature was normal and the contracture relaxed. A follow up 9 months later showed no residual difficulty.

The second case was that of a man 32 years old. Three weeks previous to examination a pain had begun spontaneously on the right side, deep in the lumbar region. It gradually increased. Also gradually increasing limp was apparent until the patient was unable to walk on admission. He had a fever, slight flexion contracture of the right thigh, pain on attempted extension, pain on pressure at the base of the right thigh on the medial aspect and a mass on the right side. The abscess was drained through the back. In 1 day the temperature was normal. A follow up 5 months later revealed no marked residual difficulty. The organism was a staphylococcus.

Similarly as in these 2 cases, the causative organism reported in the literature has been the staphylococcus most commonly the staphylococcus aureus. The streptococcus, pneumococcus or Pfeiffer's bacillus influenzae has rarely been the cause of the disease. The point of entry has sometimes been a small infected excoriation or an acne pustule, tonsils have been suspected and the appendix has been indicted. Most of the conditions have been on the right side. Small hematomas arising in connection with muscle trauma are probably predisposing factors also very strenuous work. The infection may spread into the

muscle by the hematogenous as well as the lymphatic route.

The most important symptoms are fever often high and septic, consequent impairment of the general condition and a swollen and tender muscle tumor without peritoneal irritation but accompanied by a spastic flexion contracture of the thigh with slight outward rotation. The only movement which causes pain is extension of the thigh and this may be considered pathognomonic of the disease.

Complications that may occur are collateral periurethritis or displacement of the kidney with secondary temporary hydronephrosis, perforation into the peritoneum, intestine or bladder extension below the inguinal ligament, meningitis from penetration of the dura, and metastatic infections.

In the differential diagnosis the following diseases should be considered: purulent coxitis, abscesses descending from tuberculous or nontuberculous spondylitis, osteomyelitis of the ileum, purulent ilioacral arthritis, and periappendicular and pararenal abscesses. All the bone and joint lesions should be differentiated by x-ray study as well as clinical manifestations. Periappendicular abscesses do not cause contracture of the psoas muscle as a rule whereas pararenal abscesses may cause even a severe psoas contracture. The latter differential diagnosis may be impossible but the treatment is the same as far as the abscesses are concerned.

Treatment is extraperitoneal incision and drainage of the abscess. The incision is made from the back above the crest of the ilium if the position of the abscess is high but from the front in cases of low abscesses. As the causative organisms are generally staphylococci and less often streptococci, and only in rare instances other bacteria, recovery may probably be brought about by the use of sulfonamides or penicillin alone if administration is early. The prognosis is excellent if the patient receives proper treatment. **LE ROY J. KLEINSMAN, M.D.**

Tropical Ulcer J. A. LICHTMAN CH. Proc., Cape Town, 1947 6 65

In 1945 the writer encountered a prevalent form of leg ulcer in the Natal Bantu which, since 1944, has been referred to here as "tropical ulcer." This ulcer has been described under numerous other names by various authors in the past.

The author observed 100 of these ulcers personally. The majority were chronic with a duration of from 1 to 2 months. The ulcer probably begins as an infection of a wound or sore or as a spontaneous vesicle which bursts in a few days. It usually occurs on the lower extremity below the knee. The most common sites are the anterior surface of the tibia, over the malleoli or over the dorsum of the foot. Pain was usually present but not severe. A fetid odor was characteristic. The edges of the ulcer were raised and indurated. The base was firm and adherent. A tenacious yellowish gray slough covered the floor. Beneath this, granulation tissue was exuberant. An abundant sanguineous discharge was often present.

The shape of the ulcer was often irregular or the ulcer was undermined which suggested a local acute exacerbation of a chronic process. Extension in depth was common. Multiple ulcers were often present close together—an example of autoinoculation. Lymphatic spread, toxemia, septicemia, and fever were conspicuously absent. Malignant transformation was not encountered. The surrounding skin often showed pigmentation, "crusty paving" (signs of vitamin B deficiency) and scars of previous ulcers (one ulcer did not confer immunity).

The immediate cause of an ulcer is a localized defective blood supply usually due to inflammation and infection. Various bacteria were found in these ulcers but the most common and constant were fusiform bacilli and spirochetes. Diphtheria or diphtheria-like organisms were never found, in contrast with yaws. Leishman-Donovan bodies and mycotic organisms were not found. The fusiform bacilli and spirochetes were morphologically identical with those of Vincent's angina bacillus. The frequent presence of these organisms is evidence that they were pathogenically causal and not merely saprophytic. When they were absent the patient was under active treatment or the ulcer was atypical. Other authors have often noted the presence of these organisms with the type of ulcer described. Saprophytic organisms do not invade living tissue, but in tropical ulcers various authors have noted the invasion of living tissue by spirochetes or fusiform bacilli. Tropical ulcers have been produced in volunteers by using pure cultures of fusiform bacilli. A transiently positive Wassermann reaction may occur in tropical ulcer. This has been demonstrated in cases of tropical ulcer from which pure cultures of fusiform bacilli were obtained.

Frank trauma, insect bites, and infestations are important in initiating an ulcer. Fusospirochetal organisms are common in normal and diseased mouths. The mouth has often been assumed to be the reservoir of the organisms of tropical ulcer—the mode of infection being promiscuous expectoration or intentional application of saliva as a hemostatic to an injury. The clinical and bacteriological features of human bites are seen to resemble tropical ulcer closely. Insects may mechanically transmit the organisms. The soil and water have been believed to harbor them; this may explain the usual occurrence on the legs.

Customs of dress and increased skin moisture may explain why the ulcers are confined to hot climates. There is a definite autumnal increase of these ulcers. This has been linked to dietary deficiency of protein and vitamins which is corrected during the winter.

Syphilis has been suggested as a cause for tropical ulcer. However the finding of a positive Wassermann reaction assumes less importance when it is considered that a large proportion of the native population suffers from syphilis or yaws. Besides, many cases of tropical ulcer give a negative reaction. All of the author's cases had negative blood smears for malaria. The stools in this series were negative for

hookworm ova and the unnes for bilharzic ova. It is possible that sickle cell anemia predisposes to tropical ulcers.

A dietary deficiency of calcium has been linked to an increased incidence of tropical ulcer. In the author's series avitaminosis was common among the controls but it was more marked in the ulcer cases. He believes a deficiency of nicotinic acid and riboflavin is an important predisposing cause. These vitamins are of great importance in the transfer of oxygen to living cells. Fusiform bacilli are anaerobic. Hence it is postulated that *in the competition for blood oxygen the fusiform bacilli are at a considerable advantage when these vitamins viz. nicotinic acid and riboflavin are deficient*.

With regard to age, school children predominated in the author's series. This may have been due to the teachers sending them to the hospital. Males were found more frequently in the ratio of 14 to 9. This may reflect the traumatic factor. Interestingly in the autumnal ulcer season, when dietetic factors are important, the sex incidence is almost equal.

In summary fusospirochetal organisms are believed to be the exciting cause of tropical ulcer. Access to tissues is gained through trauma to which the legs are prone. Deficiency of nicotinic acid and riboflavin is believed to be an important predisposing cause in that these deficiencies predispose to an anaerobic condition in the tissues.

JAMES WEAVER M D

Paths of Cancer Biotherapy N G KLYUKVA. *Am Rev Soviet M.*, 1947 4 408.

Biotherapy of malignant neoplasms falls into 3 categories

1 The action of folic acid. Prolonged use of folic acid has caused a regression of mammary cancer in 40 per cent of treated mice. No information is available regarding its effectiveness in the treatment of cancer in human beings.

2 The action of products of bacterial origin. The polysaccharide fraction from the *Bacillus prodigiosus* proved to be highly toxic to animals and man. Its injection was followed by fever, fall of the blood pressure, anuria, cardiac decompensation and collapse. It appears that products of bacterial origin at present, fail to give positive results.

3 The action of the South American trypanosome, *Schizotrypanum cruzi*. In a normal animal trypanosomes multiply in the heart, spleen, liver, bone marrow and lymph glands. In an animal with malignant growth, the trypanosomes are absent from these organs, and are concentrated in the neoplasm. They multiply there in large numbers and are often found within the cell.

The experiments made on white mice with transplanted sarcoma 180 showed that the strain had a potent inhibitory action. The degree of inhibition was directly proportional to the duration of the trypanosome infection. From 7 to 8 days after the injection of trypanosomes, a cessation of tumor growth could be noticed. On the eleventh day 50

per cent of the animals had no tumors, and 14 days later 85 per cent of the animals showed tumor regression while 92 per cent of the control groups showed actively growing sarcomas. The author reports the use of the cancerolytic substance KR. Favorable results were obtained in 10 patients with cancer of the larynx, in 3 with cancer of the cervix, and in 3 with cancer of the breast.

TABLE OF COMPARISON

Anticancer substance KR	Polysaccharide fraction
1 Is contained in the body of the trypanosome <i>schizotrypanum</i> .	1 Is contained in the filtrates of the culture of the <i>Bacillus prodigiosus</i> .
2 Acts on cells of an experimental implanted sarcoma, cancer, and spontaneous adenocarcinoma.	2 The same.
3. Destroys cells of malignant human neoplasms.	3 Inconclusive.
4. Effect directly proportional to the dosage of the injected substance and the number of injections.	4 Effect directly proportional to the dose of the injected substance and inversely proportional to the number of injections.
5 Disintegration of the nucleus and protoplasm of the cancer cell into separate fragments, lysis of the cell, and replacement by connective tissue.	5. Formation of a hemorrhage in the cancer and a necrosis of the cancer cells.
6 Parenteral introduction of cancerolytic doses into man is not toxic.	6 Therapeutic doses are highly toxic.
7 Extracted from the body of the trypanosomes together with a protein and carbohydrate fraction.	7 Represents a molecule of a polysaccharide.

TABLE OF CONCENTRATION OF KR AND DOSAGE

1 Number of cells in 1 c.c. of the host's plasma—5,000,000
2 Number of cancerolytic units (C U) in 1 c.c. of the host's plasma—5
3 Dosage of one injection (in units)—from 30 to 35
4 Maximal number of injections in a course of biotherapy (in units)—from 45 to 50
5 Maximal number of cells used in one course of treatment—755,000,000
6 Maximal doses of KR given in one course (in units)—755

The experiments showed two phases (1) regression and absorption of the malignant tissue following the action of the cancerolytic substance, *schizotrypa*

num (known as KR) and (s) regeneration, shown by an increase in fibroblasts and of fibrosis. The correlation of cancerolysis and of fibrosis determines the outline of the biotherapy

LEE PULLER, M D

EXPERIMENTAL SURGERY

Homotransplantation of Fetal Skin. DONALD E. BARKER, *Arch. Path. Chic.* 1947 44: 166.

Because of the previously reported conflicting results in the homotransplantation of fetal skin an attempt was made to compare the results of homotransplantation of fetal and adult skin. Black and white guinea pigs weighing from 8 to 13 ounces were used as recipients. A 1 millimeter square of black skin from each fetus and each adult was transplanted to a white rump area. The fetal skin was obtained from fetuses 1 to 7 cm. in length immediately after cesarean section. For the transplantation of adult skin guinea pigs from 4 to 5 months of age were used.

It is apparent, from the results obtained in this series of experiments, that the younger fetal skin is not as well prepared to withstand transplantation as the older fetal skin. The percentage of primary takes when the older fetal tissues were used was comparable with that attained when adult tissue was used. The main difference between older fetal tissues and adult tissue is that the fetal skin exhibits early proliferation and multiplication of the cells with enlargement of the graft, while the adult grafts usually do not increase in size. In the guinea pig the use of fetal skin for permanent transplantation is no more successful than that of adult tissue. The early proliferation of such transplanted fetal skin is of short duration and is followed either by a rapid melting away of the graft or by its slow regression.

Pigment Changes in Experimental White Thymic Skin Grafts. DONALD E. BARKER, *Arch. Path., Chic.*, 1947 44: 163.

Previous experimental work by Loeb and others has produced divergent opinions on the invasion of pigment into surrounding tissue after skin grafting. With this in mind the author has restudied the problem with the use of black and white guinea pigs. The hair was clipped and the skin shaved. With a sterile cork borer 17 mm. in diameter two circular areas were marked out, one in black and the other in white skin. The skin so outlined was excised and each piece was transferred as a free graft, the black graft to the white area and vice versa. The grafts were sutured in position and dressed with petrolatum gauze and a sea sponge pressure dressing. The dressings were changed at the end of 12 days and the grafts were observed periodically from then on.

In 11 of 50 guinea pigs, takes of both the black and the white grafts were obtained and the observations reported were made on this group of 11 animals. During the first 4 weeks following transplantation the grafts shrank to about one-half their original size. When the shrinkage had ceased the pigment of the black graft gradually invaded the surrounding white area. This extension of the black pigment continued for as long as 93 days. In contrast to this, in all 11 animals the white graft was gradually invaded by the surrounding black pigment until the graft was no longer visible. In 9 of the 11 guinea pigs this invasion of the white graft was completed within 60 to 80 days. The hair growth of the grafts was sparse, but the hair grew out of the grafts in the original direction of the growth. It was noted that in the case of the white grafts, white hair continued to emerge from the grafted area for as long as 5 months even though complete pigmentation of the original white graft had taken place.

PULMONARY RESECTION FOR ABSCESS OF THE LUNG

ROBERT P. GLOVER, M.D. and O. THERON CLAGETT, M.D., F.A.C.S.
Rochester, Minnesota

THE past ten years have witnessed a marked and gratifying improvement in the treatment of pulmonary disease. Especially has this been true with regard to the various forms of suppuration. Prior to this time the prognosis of lung abscess was dismal indeed. Conservative measures alone were rewarded by a mortality rate ranging from 35 to 70 per cent and less than half of those who survived were cured (9, 10, 23, 24). The addition of bronchoscopic and surgical drainage to the existing medical regimen lowered the mortality rate considerably but asymptomatic cures still obtained in less than 50 per cent (2, 4, 5, 6, 8, 15, 16, 22, 23, 25). It became apparent that as long as a conservative and supportive program of some 6 to 12 weeks existed before the institution of surgical treatment no better results could be anticipated. The impetus for this change in thought was supplied by Neuhoef and his associates (17, 20) and a large measure of credit is due them for the increasing reduction in mortality and morbidity of late. They showed that when the problem of lung abscess is treated as surgical from the onset with the employment of immediate or early drainage deaths can be reduced to less than 5 per cent with cures ranging correspondingly high. These results have been confirmed by many others including Betts and Overholt and Rumel.

Unfortunately these facts have not been fully appreciated by those physicians who are

in a position to deal with such cases at their inception. The advent of chemotherapy and the antibiotics has further tended to postpone a more definitive surgical attack so that there is a tendency to revert to the so called more conservative attitude in the hope that newer drugs can accomplish cures denied to earlier medical regimens. In an effort to forestall any such fallacious thought this study was undertaken. Our attempt is twofold in character. It will evaluate the results of prolonged conservative treatment with or without chemotherapy before surgical intervention and at the same time indicate what can be accomplished by pulmonary resection in lieu of over-optimistic medical care.

During the 10 year period from January, 1937 through December, 1946 pulmonary resection has been performed in 37 cases of lung abscess at the Mayo Clinic. These cases were taken from a large number in which resection was performed for pulmonary suppuration. They represent only those in which the diagnosis from the onset was that of lung abscess exclusive of underlying pathologic changes such as pre-existing tuberculosis, malignant lesions or bronchiectasis. The difficulties attendant on excluding pre-existing bronchiectasis can be readily appreciated. In short however all cases considered in this paper are those in which the patients were well before the present illness without history of previous pulmonary disease and in which disease began with acute symptoms during

It became apparent that as long as a conservative and supportive program of some 6 to 12 weeks existed before the institution of surgical treatment no better results could be anticipated. The impetus for this change in thought was supplied by Neuhof and his associates (17, 20) and a large measure of credit is due them for the increasing reduction in mortality and morbidity of late. They showed that when the problem of lung abscess is treated as surgical from the onset with the employment of immediate or early drainage, deaths can be reduced to less than 5 per cent with cures ranging correspondingly high. These results have been confirmed by many others, including Betts and Overholt and Rumel.

Unfortunately these facts have not been fully appreciated by those physicians who are

in a position to deal with such cases at their inception. The advent of chemotherapy and the antibiotics has further tended to postpone a more definitive surgical attack so that there is a tendency to revert to the so called more conservative attitude in the hope that newer drugs can accomplish cures denied to earlier medical regimens. In an effort to forestall any such fallacious thought this study was undertaken. Our attempt is twofold in character. It will evaluate the results of prolonged conservative treatment with or without chemotherapy before surgical intervention and at the same time indicate what can be accomplished by pulmonary resection in lieu of over-optimistic medical care.

During the 10 year period from January 1937 through December 1946 pulmonary resection has been performed in 37 cases of lung abscess at the Mayo Clinic. These cases were taken from a large number in which resection was performed for pulmonary suppuration. They represent only those in which the diagnosis from the onset was that of lung abscess exclusive of underlying pathologic changes such as pre-existing tuberculosis, malignant lesions or bronchiectasis. The difficulties attendant on excluding pre-existing bronchiectasis can be readily appreciated. In short, however, all cases considered in this paper are those in which the patients were well before the present illness without history of previous pulmonary disease and in which disease began with acute symptoms during

which the diagnosis of lung abscess was made primarily and progressed to various stages of chronicity under medical management including repeated bronchoscopic aspirations and dilatations chemotherapy and administration of penicillin.

In 20 cases abscess occurred during the course of a respiratory infection usually stated as being pneumonia. The presenting symptoms in all 20 cases were chills fever cough sputum frequently blood tinged and pleurisy. In 11 cases the abscess followed the administration of an inhalation anesthetic agent, most frequently in operations about the mouth such as tonsillectomy extraction of teeth and drainage of sinuses. In 5 cases a foreign body was found in the resected specimen in 3 of these the history of aspiration had been obtained but in 2 this finding was totally unsuspected. In the 1 final case the abscess followed an injury to the thoracic wall in which a segment of rib had pierced the lung causing hemoptysis infection and cavitation but no hemothorax.

All but four of the patients in the entire series had been given at least one course of chemotherapy or penicillin (some as many as six) and in all cases both therapeutic and diagnostic bronchoscopy had been performed repeatedly. In addition 7 of the patients had undergone previous surgical procedures: 2 had artificial pneumothorax 2 had rib resection and open drainage twice 1 had open drainage once 1 had open drainage followed by a six rib thoracoplasty and 1 had an empyema drained—all the foregoing without lasting benefit. The average elapsed time from diagnosis to resection for the 37 cases was 18 months, the extreme being 11 years indicating that this presentation obviously concerns the chronic form of lung abscess, a condition which calls for resection of destroyed tissues and not drainage such as would be considered in dealing with an early uncomplicated abscess. The relationship of surgical drainage and resection will be discussed later.

ANALYSIS OF MATERIAL

Thirty seven patients who had lung abscess in various stages of chronicity underwent pulmonary resection. There were 2

cases of partial resection 16 of lobectomy 3 of bilobectomy and 16 of pneumonectomy.

Partial resection. It is relatively rare to find the surrounding pathologic changes of pneumonia fibrosis, and bronchiectases which accompany chronic abscess so localized as to permit resection short of lobectomy. We do not advocate such an approach feeling that complications are far more likely to arise when infected tissue acute chronic or macroscopic, is traversed. These 2 cases presented unusual findings. In the first a segmental resection of the superior division of the right lower lobe was possible as this segment was anomalously separated from the lower lobe almost forming a fourth right lobe. The result was excellent. In the second case there was an abscess involving small portions of both the right upper and middle lobes in the region adjacent to the fissure. This was excised *in toto* for immediate pathologic examination a malignant lesion being feared. A small empyema developed but healed after drainage and the patient is now working normally without symptoms. In these cases the mortality rate was 0 per cent complications occurred in 50 per cent and the present status is 100 per cent cured.

Lobectomy. As a result of aspiration and infection the inflammatory changes of lung abscess usually occur initially in one bronchopulmonary segment. Without prompt drainage lymphatic and bronchial spread will take place so that all the segments within a given lobe may become involved within a short time. Whereas it is frequently not necessary—drainage sufficing—and even inadvisable to resect a segment of a lobe the natural divisions of an entire lobe lend themselves admirably to excision. Thus the entire diseased region may be removed the inevitable regions of parenchymal destruction that result from attempted drainage at this stage are avoided and the patient is given a better chance of obtaining an asymptomatic cure. In 16 cases lobectomy was performed. There were complications in only 2 cases, in both of which resection was performed in 1938. Mass ligation technique was used at that time and bronchopleural fistula with empyema developed in each instance. Both fistulas were drained and after a

Note residual parenchymal scarring.

period healed completely. The patients are now asymptomatic having resumed their former work—one as a blacksmith, the other as a student. In these cases the mortality rate was 0 per cent, complications occurred in 12.5 per cent, and the present status is 100 per cent cured.

Bilobectomy. When the disease process has progressed to involve more than one lobe, it may be possible to resect the lower and middle lobes on the right side, preserving the function of the upper lobe. Bilobectomy may also be resorted to when the disease, although localized in one lobe, has involved a second by inflammation and adhesions so as to preclude the safe removal of one without the other. In 3 cases bilobectomy was performed in 1 for the technical reasons mentioned previous-

ly, and in 2 because of the extensive disease process. The patient in one of the latter cases died 48 hours after operation from shock with pulmonary edema. This patient had undergone open drainage of an interlobar empyema 1 month previous to resection. At final operation the lower and middle lobes were frozen in adhesions and an abscess was found perforating onto the diaphragm. The resection was difficult; contamination was widespread; 2,500 cubic centimeters of whole blood was given during operation and the ensuing 24 hour period and was supplemented by 2,250 cubic centimeters of intravenous fluid. An additional 2,300 cubic centimeters of intravenous fluid was given on the second postoperative day. It is quite possible that in the effort to overcome operative shock the pul-

which the diagnosis of lung abscess was made primarily and progressed to various stages of chronicity under medical management including repeated bronchoscopic aspirations and dilatations chemotherapy and administration of penicillin.

In 20 cases abscess occurred during the course of a respiratory infection usually stated as being pneumonia. room in good condition but died suddenly in the elevator on the way to her room. It is possible that mediastinal flutter was responsible for this fatality although intrapleural pressures were determined and the mediastinum was adjusted to the preoperative state before the patient left the operating room as is our routine procedure. In this group of cases the mortality rate was 37.5 per cent.

Complications of those patients who survived operation were even more distressing. In 3 additional cases the patients died from brain abscess within 5 months of dismissal. One of these patients had experienced two Jacksonian seizures before operation and 1 died 5 months later after an unsuccessful

attempt to drain the cerebral suppuration. Whether metastasis to the brain had occurred before operation or as a result of operation in the 2 cases without preoperative signs of cerebral irritation is a matter of conjecture only. With the addition of these fatalities our mortality rate is revised upward to 56.2 per cent. In another 2 cases empyema developed. In 1 case it occurred 2 months after dismissal from the hospital. Repeated aspiration has obliterated the pleural space in 1; the other required open drainage and thoracoplasty and is still draining slightly. In a sixth case thoracoplasty was required within a year after operation because of cough and dyspnea from mediastinal shift and overexpansion of the

Not increased damage to lung.

monary edema found at postmortem examination was produced. In these cases the mortality rate was 33.3 per cent, complications occurred in 0 per cent, and the present status is 66.7 per cent cured.

Summary of these 21 cases in which conservative resection could be carried out reveals a mortality rate of 4.8 per cent and a complication rate of 14.3 per cent. The complications responded to appropriate treatment. Thus in 20 of the 21 cases the final result was an asymptomatic cure.

These results are in sharp contrast to the following obtained by pneumonectomy. When infection has been permitted to ravage an entire lung with the production of varying degrees of fibrosis, bronchiectasis, bronchosteno-

sis and atelectasis, resort to surgical treatment becomes in many instances a last-ditch stand.

Pneumonectomy. In the remaining 16 cases total pneumonectomy was performed. There were 6 postoperative deaths, 3 within 24 hours from shock, the fourth within 4 days from a stroke, necropsy revealing an infarct in the left hemisphere of the cerebrum. The fifth patient died on the table from hemorrhage. This patient had undergone 5 previous operative procedures elsewhere, including several open drainages and a six rib thoracoplasty. In these 5 cases pneumonectomy was performed more than 3 years ago. In 2 of them more than 5 years ago. In the sixth case pneumonectomy was done recently. The patient, a child aged 6 years, left the operating

contralateral lung. Complications occurred in 37.5 per cent of the cases in which pneumonectomy was performed.

The marked discrepancy in results between these two groups is obvious. It cannot be explained on the basis of magnitude of operative procedure alone for such results are at marked variance to our approximate over all 2:1 mortality ratio for pneumonectomy versus lobectomy. We believe the crux of the situation lies in the preoperative condition of the patient. The individual who has lost the function of an entire lung because of widespread suppuration and has been subjected to a long period of toxicity and debility will inevitably undergo extensive surgical manipulation with

greater risk. If such is the course of conservatism it becomes paradoxical and should be regarded rather as the more radical approach. The basic principle of attacking irreversible tissue damage early before vital body reserves are depleted should remain inviolate.

COMMENT

The trend in very recent years in the treatment of chronic lung abscess has been away from open drainage and toward pulmonary resection. From 1921 to 1937 the mortality rate for drainage in this type of case ranged between 21 and 45 per cent (12). More recently a number of reports have appeared stressing the rationale of excision pointing out

Fig. 6 a, Multilocular abscess in the posterior segment of the left upper lobe. b, Roentgenogram after left upper lobectomy. that in spite of the poor condition of the patient resection particularly lobectomy can be accomplished with a low operative risk and with a much higher percentage of asymptomatic cures (17-11). Landskog (13) in 1944 presented a series of 24 resections with excellent results. Of 14 patients who underwent primary lobectomy 1 died a mortality rate of 7.1 per cent. Twelve obtained good results and 1 was still under treatment. Of 10 secondary resections there were no operative deaths, 2 patients dying later of brain abscess and streptococcal sepsis. Our results are in complete accord with these observations and we feel that they present additional arguments in favor of regarding lung abscess as a surgical problem from the outset.

The statement has been made repeatedly in the literature that 25 to 30 per cent of lung abscesses will clear by medical means alone. We agree with this premise but as the course of any given case is unpredictable it is felt that surgical consultation should be sought from the outset so that the optimal time for intervention may not be overlooked. The relationship between drainage and resection will in time under these circumstances become clear. Resection should supplant drainage as long as cases of lung abscess are presented to the surgeon. In the chronic or complicated stage as has been true in great measure to date. Should the patient be seen early and the lesion be found to be localized without evidence of widespread secondary changes (fibro-

It spirals of crushed peanut from bronchoscopy attempt 1 led to removal of pus at right lower lobectomy dismissal on tenth postoperative day.

4. bronchiectasis bronchostenosis atelectasis) open drainage is the reasonable procedure. Under this management time and thorough follow up with bronchography alone will determine whether the parenchymal fibrotic scar resulting from drainage will remain a future source of bronchiectatic change with its pooled secretions and attendant symptoms. In the latter eventuality resection will replace open drainage in all forms of lung abscess except those in which the disease is fulminating and drainage becomes a life-saving procedure.

INDICATIONS FOR PULMONARY RESECTION

At present our indications for pulmonary resection in cases of lung abscess are

1. Persistent symptom due to pathologic changes secondary to open drainage.
2. Multiple or multiple abscesses.
3. Abscesses associated with secondary changes such as fibrosis bronchiectasis bronchostenosis, or atelectasis.
4. Abscesses so located anatomically as to be inaccessible to adequate drainage.
5. Abscesses in which the diagnosis of malignancy is entertained.
6. Abscesses associated from the onset with excessive bleeding.
7. Abscesses in children.
8. Abscesses secondary to foreign bodies unretrievable by bronchoscopy.

In this respect our experience has been similar to that of Landskog and Woods and McCraith.

1 Persistent symptoms of cough expectoration or hemorrhage obviously indicate the presence of residual or superimposed infection in regions of fibrosis and ectasia resulting either from undrained regions of the original disease process or from the traumatic sequelae of surgical drainage. Were all lung abscesses treated by open drainage followed at intervals by bronchography we have no doubt that a large percentage would reveal bronchial and parenchymal distortion and dilatation. When such conditions prevail resection affords the only lasting form of treatment. Such a case is illustrated in Figures 1, 2 and 3.

2 Multiple or multilocular abscesses as a rule indicate such extensive irreversible damage that resort to surgical procedures short of resection is an invitation to continued bronchiectatic symptoms (Fig. 4a and b and Fig. 5a frontispiece).

3 Those abscesses which are seen by the surgeon for the first time after the secondary changes of fibrosis bronchiectasis bronchostenosis or atelectasis have developed will not be relieved by any treatment other than resection. Surgical drainage is designed to evacuate cavities but cannot be expected to influence widespread parenchymal degenerative and reparative processes (Fig. 4c and d).

4 There are many abscesses so located within the lung that even though they are in contact with parietal pleura at some point adequate drainage cannot be maintained because of overlying structures such as the scapula. In addition a number of abscesses which present on the mediastinal interlobar or diaphragmatic pleural surfaces are more suitable for resection than for drainage. In some of these cases it may be in order to attempt drainage primarily reserving excision for a time when the extent of the underlying pathologic changes may be more clearly demonstrated (Fig. 6a and b and Fig. 5b frontispiece).

5 Although this paper is not primarily concerned with abscesses secondary to a malignant lesion it is strictly in order to comment that particularly in patients more than 40 years of age when such a diagnosis is entertained the only procedure tenable is exploration and resection.

6 In 19 of the 37 cases in this series hemoptysis of some degree was present from the onset of the disease. In 6 it occurred repeatedly in profuse amounts and we believe that this symptom alone regardless of the extent of the associated pathologic changes is an indication for resection. There have been many reports of fatal hemorrhage following open drainage for lung abscess and it is our feeling that forewarned should be forearmed for in such cases in all likelihood the hemorrhagic trend will continue (Fig. 6c and d and Fig. 5c frontispiece).

7 There may be some controversy over including all lung abscesses in children in the list of absolute indications for pulmonary resection. Our experience has suggested that such a course is reasonable on several grounds. First children tolerate resection extremely well. Second, there is some evidence that regeneration and compensation occur in the remaining lobes, if we may apply the experiments of Longacre and Johansmann on animals to human beings. Third it is felt that should regions of parenchymal damage remain after drainage they may be the source of continued infection and the focus from which additional lung damage may arise as the child grows older. Fourth long continued drainage is frequently difficult to manage especially in the very young, and as such may be inadequately cared for by parents and physician alike (Fig. 7a and b).

8 Occasionally experienced bronchoscopists are unable to remove an aspirated foreign body from the depths of the small bronchial radicals. Especially is this true when crushed pieces of peanuts or other food particles have been insufflated. Abscesses on this basis are best resected to insure the removal of the foreign body (Fig. 7c and d). In 2 cases in this series large foreign bodies in the form of a piece of fall grass and a bone were aspirated unknown to the patient and were found only on dissection of the specimen (Fig. 5d frontispiece).

SUMMARY

In 37 cases primary lung abscess in various stages of chronicity was treated by pulmonary resection. The elapsed time from the origi-

nal diagnosis to surgical excision averaged 18 months. In the 21 cases in which a conservative resection (lobectomy or less) could be performed there was 1 death (mortality rate 4.8 per cent) despite the wasting and general debility of the patients when admitted for treatment. In the remaining 20 cases the results were good and are regarded as asymptomatic cures. In contrast of the 16 cases in which total pneumonectomy was performed in only 7 was a good result obtained and in 3 of these it was delayed considerably by complications. There were 6 deaths attributable to operation (mortality rate 37.5 per cent) and 3 late deaths resulting from brain abscess.

We believe that if the problem of acute lung abscess is considered as surgical from the outset and the optimal time for intervention is recognized and acted on with dispatch the problem of chronic lung abscess will virtually be eliminated. Until such a time pulmonary resection is the treatment of choice for supuration of long standing. It is our opinion that bronchographic follow up of patients treated by open drainage will reveal that a significant number are left with residual parenchymal and bronchiectatic changes, which in all probability will lead to further symptoms at some future date. This is especially true when abscesses are drained in the chronic state or after secondary changes have taken place. For this reason pulmonary re-

section should take preference over open drainage in most cases seen by the surgeon at the present time.

THE BRONCHIAL ARTERIES

An Anatomic Study of 150 Human Cadavers

EARL W. CAULDWELL, M.D., ROBERT G. SIEKERT, M.B., RICHARD E. LININGER, M.D.
and BARRY J. ANSON, Ph.D. (Med. Sci.) Chicago, Illinois

THIL bronchial arteries which provide the systemic nutrient supply to the lungs have been studied in their intraparenchymatous course by many anatomists and physiologists¹ but their gross topography has been inadequately considered in systematic studies of human angiology. The relative inaccessibility of these vessels makes them difficult to demonstrate in the dissection's routine anterior approach to the thoracic viscera and only when abnormally affected are they observed at the autopsy table. Consequently the literature is replete with conventionalized descriptions but neither detailed nor comprehensive information is available.

These vessels were known to Galen from dissections on sub-human types but were not specifically named (Miller 1906). Their identity was denied by Columbus (1559) and reaffirmed by Marchettus in 1656. The discovery of the bronchial arteries as vascular conduits separate from but anastomosing with the pulmonary system was claimed by Ruysch in 1721. His description however represents a rediscovery with a more accurate text and the first illustrations of the arterial distribution. Accurate descriptions of their origin and course and some of the variations in pattern are to be found in Albertus Haller's *Icorum Anatomicarum* (1747); this account represents a heritage little modified in subsequent treatises of anatomy and surgery. The monographs of Fickel (1743) and Susloff (1895) are relatively unknown to the student and are not readily accessible. The accounts of Boyer (1815) and Bichat (1819) closely follow that of Haller and are more adequate than many

appearing in later texts. In Tiedemann's excellent *Tabularum Arteriarum* (1822) bronchial arteries are portrayed as arising from the concavity of the aortic arch and from the proximal portion of the descending aorta and coursing anterior to the trachea to the corresponding surface of each primary bronchus. This most unusual pattern has been uncritically copied into a succession of standard works by Cloquet (1825), Smith (1835), Galet (1853), Quain (1866), Hoffmann (1878), Testut (1911), Rauber Kopsch (1919) and Morris-Schaeffer (1942) despite the fact that it is inconsistent with the accompanying texts. Modern anatomy books perpetuate Haller's account of variations in origin of the bronchial arteries so that the right subclavian, superior intercostal, inferior thyroid and internal mammary arteries are regularly included in the discussions of anomalous sites of origin. Original reports of variable origin of these vessels other than undocumented textbook statements have implicated the right subclavian (Haller 1747, Henle 1876, Fredenc 1897, Menke 1936), the left subclavian (Meyer 1857, Turner 1862, Hewitt 1930, Schneider 1934), the internal mammary (Zagorsky 1834, Quain 1844, Fredenc), the superior intercostal (Ruysch, Quain, Luschka, 1863, Poupartin 1909) and the innominate (Quain, Romankevich 1931).² Origins of bronchial ar-

¹Several descriptions in the literature are ambiguous. The bronchial artery patterns in cases reported by Jacobson (1866) and LeGros Clark (1897) may be variably interpreted. Jacobson (cited by Christeller) presented a case of congenital heart disease with dilatation of the bronchial arteries and of a branch described as the superior pericardiac artery; whether the latter vessel represents an anomalous bronchial artery or an abnormally dilated anastomosis between the bronchial and pericardiophrenic arteries is not clear. LeGros Clark likewise described a case of congenital heart disease with dilatation of the bronchial arteries and "the branch from the internal mammary artery which accompanies the phrenic nerve was nearly equal in size to the parent trunk, and expended itself principally in the adjacent adherent lung." This was interpreted as an anomalous bronchial artery by Hovelacque, but as in the former case, may merely represent a dilated pericardiophrenic artery; an anastomotic relationship with the bronchial vessels. (Continued on next page.)

Contribution No. 481 from the Anatomical Laboratory, Northwestern University Medical School.

For a discussion of the intrinsic anatomy of the bronchial arteries the reader is referred to Miller's classical monograph on *The Lung* (1911). A brief historical survey of the problem of bronchial and pulmonary arterial relationship is provided by Berry Brunsford and Daly (1931).

teries from the distal portion of the thoracic aorta have recently been reported by Schall (1926) and Natucci (1939) and from the abdominal aorta by Cioni (1939).² A critical examination of these cases indicates that the vessels described represent anomalous pulmonary rather than bronchial arteries. Anomalous pulmonary arteries constitute surgically important structures and have been specifically described by McCotter (1910) who reviewed the literature to 1777 Batts (1939) Harris and Lewis (1940) and Arce (1943).

In 1924 Nakamura examined the thoracic aortae of 129 cadavers to determine the sites of origin of the bronchial arteries but the restricted topographic nature of the study obviated a consideration of vascular patterns. He classified bronchial arteries on the basis of origin into 3 major types: Type A, arteries arising directly from the aorta (33 cases); Type B, arteries arising in part directly in part indirectly from the aorta (103 cases); and Type C, arteries arising indirectly from the aorta (3 cases). Hovelacque, Monod and Evrard (1936) described the course and distribution of these vessels, and illustrated some variations in pattern without tabulating any portion of their data.

The comparative anatomy of the bronchial arteries is represented by studies on the dog (Kuttner 1878 Miller 1925 Berry Brailsford and Daly 1931) and guinea pig (Willis, 1919) based principally on injection preparations (see footnote 3).

Fickel (743) described common bronchial artery to both lungs arising from subclavian, whose side, however, was not specifically given. It may be assumed, from the context, to have been the left.

Turner (263) described case of right aortic arch, and anomalous site of origin of the left subclavian and left bronchial arteries from retroesophageal pouch like trunk rising from the left side of the descending part of the arch. In contrast, Zagorsky (834) described right subclavian from the left side of the aortic arch. The anomalous subclavian gave rise to vertebral artery which in turn provided common trunk for internal mammary and deep cervical arteries. The right bronchial artery arose from the aberrant internal mammary vessel.

Highly aberrant forms appear in the older literature: common trunk from the abdominal aorta immediately proximal to the celiac axis ascends through the esophageal hiatus to bifurcate and supply the lower lobes of both lungs (Mansueto, 80). Trunk arising from the celiac axis is common with the right phrenic plexus through the esophageal hiatus to bifurcate and supply the dorso-lateral aspect of both lungs (Heyfelder, 443).

Brown (911) illustrated right accessory pulmonary artery from the right inferior phrenic artery in cat. Winogradsky (990) described anomalous origins for these arteries from the abdominal aorta in the dog and martin. This is apparently the normal vascular pattern in reptiles (Hinkle, 876).

The embryology of these arteries has not been subjected to systematic study and our present information is chiefly speculative in character.⁴

It has been long known that alterations in the physiology of the pulmonary arterial circulation have an effect on the bronchial arterial system. Virchow (1851) demonstrated that long standing obstruction of a pulmonary arterial branch to one lobe led to dilatation of the bronchial arteries and the participation of the bronchial arteries in the pathologic processes resulting from pulmonary stenosis and atresia has been more recently described by Christeller (1917) East and Barnard, (1937), Schopper (1938) and Greenspon and Leamas (1939). Christeller reviewed a series of 35 cases, collected from the clinical literature between 1815 and 1905 emphasizing the function of the bronchial arteries in collateral circulation of the lung in the presence of pulmonary artery obstruction. With the impetus provided by Miller's work on the intrinsic an-

According to Evans (900) nothing has been ascertained concerning the development of the bronchial arteries, and examination of the literature after 900 reveals no specific work on the embryology of these vessels. Because of the close relationship of bronchial arteries to intercostal arteries, arising in company with the latter or from corresponding portions of the thoracic aorta, clues to the embryonic origin of the right bronchial vessels may be gained by consideration of intercostal artery development.

Dorsal sprouts emerge strictly intersegmental pulsed from the primitive duplicated and unbranched descending aorta, and course in the planes between prebifurcative segments to vascularize the spinal cord and ganglia, and eventually the body wall. Avascular position of the aortae results in their emergence by pairs. The definitive intercostal arteries are secondary derivatives of the original dorsal segmentals, and so outstrip them in growth that in the postnatal body they themselves are identified as the main branches, the original segmentals seeming to be merely their posterior rami.

Atrophy of the proximal cervical dorsal segmentals leaves the seventh segmental as the permanent trunk of origin of vertebral and subclavian arteries, the seventh segmental, though it supplies intercostal branches, functions as root of origin for the eighth cervical and first thoracic arteries. The next permanent dorsal segmental behind the subclavian is the second or third thoracic; hence, the first intercostal supplies either or both of these intertruncs.

The association of bronchial arteries with right intercostals, and occasionally with the subclavian and internal mammary arteries, would suggest secondary development of the pulmonary arterial system from the lower cervical and upper thoracic dorsal segmentals (intercostals), and from the ventral aspect of the aorta during the course of, and subsequent to, the descent of the lung into the future thoracic cavity.

The proximity of the aortic arch to the root of the left bronchus would permit easy access of visceral branches from the right to the left main bronchus (see Table I, A). The right main bronchus is accordingly separated from its aortic source by greater interval and is in closer relation to aortic branches instead, to right intercostal arteries (see Table II). The final answer to the interesting question of bronchial artery origin must await further embryologic study.

Fig. 1. Types of bronchial arterial supply 150 cadavers classification based upon origin, number and course of the vessels. Semidiagrammatic dorsal aspect.

tomic relationships of pulmonary and bronchial arterial systems, important studies were conducted on the pathologic physiology of the bronchial circulation by Mathes Holman and Reichert (1930-1932) and by Wood and Miller (1938). These authors found a consistent dilatation of the bronchial arteries in acute and chronic inflammatory processes involving the pulmonary parenchyma³ in primary carcinoma of the lung in congenital cystic disease of the lungs and in pathological and surgical occlusion of the pulmonary artery to a lobe. Following a pulmonary embolus, the

In the current series, it was observed that the bronchial arteries to lungs showing caseous necrosis and cavitation (presumably tuberculous) were increased in size in comparison with those from specimens free of gross pulmonary disease. There is specific dilatation of an artery to a particular lobe when that lobe alone is grossly involved.

bronchial arteries serve the important function of filling the circulatory beds distal to the embolus and in the presence of infection provide increased nutriment to the involved lung by virtue of its dilatation (Mathes *et al.* 1932). The participation of the bronchial arteries in traumatic affections of the mediastinum (Latimer and Willems 1928) and in syphilitic arteritis (Jacobi 1931; Pinard, Corcos and Lemoine 1937) has also been reported. In Jacobi's case there were multiple saccular aneurysms of the left bronchial arteries.

The bronchial arteries are encountered by the thoracic surgeon in the course of lobectomy or pneumonectomy but ordinarily they constitute no great obstacle to the technique (Blades and Kent 1940; Kent and Blades

1942). However their dilatation subsequent to inflammatory processes in the lung or in concurrence with congenital or pathologic destruction of the pulmonary circulation may make of these vessels hazards to be reckoned with in surgical manipulation. Certainly knowledge of their varied origins and distribution would provide a practical addition to the operator's armamentarium.

MATERIAL AND METHODS

The current study is based upon dissections of 150 adult male and female cadavers, white and negro. A posterolateral approach to the mediastinum is employed. With the body in the prone position muscles of the 9th intercostal space are transected and the parietal pleura separated as each rib (from 9th to 2nd) is successively removed by sectioning them 2.5 centimeters lateral to the costovertebral junction and along the midaxillary line. The parietal pleura is then incised along the thoracotomy like opening and removed. This procedure provides an adequate exposure of the posterior mediastinum. Subsequent dissection removes the pleura from mediastinal viscera, and exposes the bronchial arteries.

The bronchial arteries are usually first encountered as they course on or near the membranous portion of the main bronchi. When identified they are dissected proximally to

*One case of complete atresia of the bronchial artery was encountered in the course of study making a total of 5 cadavers. This specimen is discussed separately, however and is not included in the tabulation of data.

TABLE II — RIGHT INTERCOSTOBRONCHIAL ARTERIES (133 CASES)

	Cases	Percent of Cases	Percent of Total
I. First intercostal artery		1.00	1%
2nd intercostal		25	6%
3rd and 2nd intercostals		2.00	4%
1, 2nd and 3rd intercostals	3	25	10%
2nd intercostal	27	51	19.5%

3rd and (1) 4th intercostals	1	25	1%
		100.00	100%

their origin and finally into the hilum of the lung.

Representative specimens are chosen for illustration. For the purpose of clamping vascular structures are sometimes totally removed, and the trachea and great vessels mobilized to expose fully the course of the arteries. Typical examples of each variational type are shown semidiagrammatically in Figure 1 (I to IV).

OBSERVATIONS AND DISCUSSION

The bronchial arteries take origin with but few exceptions from the proximal part of the thoracic aorta arising independently in multiples from a common stem or in company with a functionally unrelated vessel. For convenience in description these vessels are tabulated quantitatively into types (Table I) into modes

TABLE III — MODE OF ORIGIN OF BRONCHIAL ARTERIES (150 CASES)

*Interbronchial trunks considered as separate vessels
 *One of these arises from the left subclavian

of origin (Tables II and III) and their approximate level of emergence from the parent trunk is recorded in topographic relationship to the thoracic vertebrae (Tables IV A and IVB)

Origins The more commonly encountered pattern Type I in Figure 1 (40.67 per cent Table I) is that described as normal in standard textbooks. In these specimens two left and one right bronchial arteries are present. In every case there is at least one bronchial artery to each lung and this simplest vascular scheme occurs next in order of frequency as Type II (21.33 per cent). The third major group Type III is characterized by bilateral duplication of the arteries (20.67 per cent of cases). These three types comprise 82.67 per cent of the arterial patterns in all cadavers studied.

In 14 cases (Type IV 9.33 per cent) the pattern is the reverse of Type I with one artery to the left and two to the right lung. The arteries to the left lung are increased to 3 with a single vessel persisting on the right side in 6 cases (Type V 4.0 per cent). A maximum number of 5 arteries is encountered in 6 cases (4.0 per cent). Of these 3 specimens pos-

Exclusive of interbronchial trunks.

From the anteroposterior aspect of the aortic arch.

Five common trunks, 3 providing one vessel to each side, dividing into left and right vessels.

*Twelve common trunks, of which divided into left and right artery.

Two common trunks.

sess 3 left and 2 right arteries (Type VI 2 per cent) and a single case demonstrates the reversed scheme (Type VII 0.67 per cent). The

remaining 2 examples have four arteries to one lung and a solitary vessel to the opposite organ. The quadruple pattern is found on the left in Type VIII (0.67 per cent) on the right in Type IX (0.67 per cent).

On the basis of sides two thirds of all right lungs are supplied by a single bronchial artery (100.67 per cent) whereas about one third of left lungs are so supplied (47.318 per cent). On the other hand 62 per cent of all left lungs are provided with two bronchial arteries, while half that number (32 per cent) of right lungs have duplicated vessels. Three arteries to the left lung are observed in 9 bodies (6 per cent) and to the right lung in but 1 instance (0.67 per cent). Four arteries supply a right and a left lung in separate cases (Table I).

Classification of bronchial arteries into types on the basis of pattern frequency may be supplemented by a consideration of the manner of origin of the vessels represented.

Type I. Two left, one right (61 cases 40.67 per cent)

- A Each arises separately (58.487 per cent)
- B Superior left and single right from common stem (1.06 per cent)
- C Inferior left and single right from common stem (0.6 per cent)
- D All three from common stem (1.06 per cent)

Type II. One left, one right (33 cases 21.33 per cent)

- A Each arises separately (58.187 per cent)
- B Both from common stem (4.57 per cent)

Type III. Two left, two right (31 cases 20.67 per cent)

- A Each arises separately (9.6 per cent)
- B Inferior left and inferior right from common stem (9.6 per cent)
- C Superior left and inferior right from common stem (8.53 per cent)
- D Two common stems (2.1 per cent)
- E Superior left and superior right from common stem (1.1 per cent)
- F Two left and inferior right from common stem (0.6 per cent)

Type IV. One left two right (14 cases 9.33 per cent)

- A Each arises separately (9.6 per cent)
- B Single left and inferior right from common stem (5.33 per cent)

Type V. Three left, one right (6 cases 4 per cent)

- A Each arises separately (5.2 per cent)
- B Superior and middle left, single right from common stem (1.1 per cent)
- C Inferior left and single right from common stem (1.067 per cent)

Type VI. Three left, two right (3 cases 2 per cent)

- A Each arises separately (1.067 per cent)
- B Superior left and inferior right from common stem (1.067 per cent)
- C Inferior left and right from common stem (1.067 per cent)

Type VII. Two left three right (1 case 0.67 per cent)

- Two common stems superior left and middle right, inferior left and right.

Type VIII. Four left, one right (1 case 0.67 per cent)

- Each arises separately

Type IX. One left, four right (1 case 0.67 per cent)

- Superior right from right subclavian, middle left and second right from common stem, third and fourth right arise separately.

The bronchial arteries to the right lung differ markedly from those to the left in respect to sites of origin from the aorta. Those to the right side arise from the corresponding lateral or dorsolateral aspect of the aorta, in the former position when separate and in the latter position separately or in combination with an intercostal. When this last named arrangement occurs, the point of origin is in longitudinal alignment with the remaining intercostal arteries (Fig 1). In cases with single right arteries this pattern obtains consistently. It does not occur regularly in cases with multiple right vessels in such specimens the superior bronchial artery is likely to arise in common with an intercostal while the inferior bronchial originates from the anterior surface of the aorta. In no case does a right bronchial artery arise from the left side of the aorta.

A right bronchial artery frequently arises in common with an intercostal artery. The term *intercostobronchial* is hereinafter applied to these vessels in order to obviate artificial and confusing distinction between parent stem and branch in the majority of cases but the difference in size is observed between the components of the bifurcated vessel. Where as embryologically the intercostal artery holds primary position (see footnote 4) the right bronchial artery is frequently of greater size than the related segmental vessel (Fig 4). The fact that the right bronchial artery frequently arises in common with an intercostal has been long known. Ruysch and Haller described this relationship. However confusion has resulted from failure to indicate accurately the intercostal vessels associated with this

Fig. 2. Bronchial arteries and related structures (Specimen A). Deep thoracic structures viewed from an anterior and slightly lateral position. The thorax has been opened by cutting away the body and xiphoid process of the sternum and the ribs from the first through the seventh. Within the thoracic cavity the following structures have been removed: pleura, heart and pericardium inferior vena cava and azygos vein, both lungs except in their hilar portions. The phrenic nerves are retracted; the ligamentum arteriosum is indicated by a cross. In this way the following ves-

sels, viscera and nerves (pertinent to the current study) have been exposed: trachea and bronchi, vagus nerves, esophagus, thoracic aorta and bronchial arteries. The bronchial arteries (Type II) arise by a common stem, one division passing to each bronchus. The right bronchial vessel crosses anterior to the esophagus, to ramify on the anterior and inferior surfaces of the corresponding bronchus. The vessel of the left side courses almost directly forward at the inferior margin of the left bronchus, ramifies then pass to the anterior surface.

Figs 3a to 3c. Bronchial arteries and related structures (Specimen B). Figure 3a, an oblique view from the front and right. Figure 3b, obliquely viewed from the opposite side. Figure 3c, diagram of the bronchial and intercostobronchial sources (Type III) from the front. In Figures 3a and 3b the aorta has been removed except in the tracheobronchial area. In Figure 3a the arch of the azygos vein has been transected and this vein turned laterally, right bronchus has been pulled forward, as has also the esophagus, to demonstrate the vessels sent from the intercostobronchial artery to the right bronchus and the vessel of aortic origin which bifurcates to supply both bronchi. In Figure 3b the aorta has been retracted to show in addition to the arteries just described, left bronchial vessel. On each side ramify from the chief sources do not merely course distalward with bronchus, but also turn proximalward to supply the trachea. Some branches are given off to the esophagus (Fig 3b).

pattern. Many authors of textbooks classify the segmental arteries on the basis of the intercostal spaces supplied (posterior intercostal arteries); others identify them more satisfactorily on the basis of their relative position as aortic derivatives (aortic intercostal arteries). To provide needed information of accurate nature and incidentally to indicate the discrepancies which can arise from the designation of posterior intercostal arteries as reference sites data have been tabulated on the right intercostobronchials (Table II).

One or more right intercostobronchial arteries are found in 133 cadavers (88.7 per cent

Table II). A right bronchial artery is associated with a single intercostal in 129 cases (86 per cent). In 4 cases (2.7 per cent) each of 3 right bronchial arteries arises in common with an intercostal; in 3 in common with the first and second aortic intercostals and in 1 with the first and third. In 17 cases (11.3 per cent) the right bronchial arteries are in no way associated with intercostals; they arise from the aorta or subclavian⁷ either separately or

Winkel (1835) describes branches from the subclavian as corresponding internal mammary arteries as "superior bronchial arteries." Other authors generally refer to these as "accessory bronchial" or "anterior bronchial" arteries in contrast to "posterior" or "inferior" vessels; the latter terms referring to the usual arteries of aortic or intercostal origins.

CAULDWELL ET AL. BRONCHIAL ARTERIES

Figs. 4 and 5. Bronchial arteries in relation to adjacent mediastinal structures (Specimen C and D, respectively). Anterolateral views (Fig. 4 from the left, Fig. 5 from the right). In Figure 4, left, the upper lobe of right lung has been drawn aside to expose an unusually large intercostobronchial artery beneath the arch of the azygos vein (here transected) maintaining its diameter as the right bronchial and continuing as an attenuated first aortic intercostal. In Figure 5, all pulmonary tissue has been removed to show the two left bronchial arteries of direct aortic origin and an unusual left superior bronchial arising from the subclavian (Type V). In addition to its supply to the left superior lobar bronchus, the left superior bronchial artery sends a descending ramus along the corresponding surface of the esophagus, thus supplying the supply of direct aortic and intercostal derivation.

in company with other right or left bronchial vessels.

Of an overall total of 205 right bronchial arteries (to 150 right lungs) 137 (66.8 per cent) in 133 cases are components of intercostobronchial trunks. The remaining 68 vessels (33.2 per cent) occurring in 60 cases, are unrelated to the intercostal vessels.

The right bronchial and first aortic intercostal arteries are derived from a common stem in 117 cases. This represents 78 per cent of total cases (150) or 88 per cent of those (133) demonstrating intercostobronchial relationship.

The first aortic intercostal spaces from first to fourth as solitary or combined trunks. In 82 cases supplies intercostal spaces from first to fourth as solitary or combined trunks. In 82 (of 117) cadavers a single intercostal space most vascularized the third being the space most commonly supplied in this manner (Table II). In 31 (of 117) cases, an intercostal artery bifurcates distal to its emergence from an intercostobronchial stem to supply two adjacent interspaces the second and third spaces being

those most frequently cared for in this manner. In only 4 cases (of 117) are 3 adjacent interspaces supplied by a single derivative of an intercostobronchial artery.

The second aortic intercostal artery is associated with a right bronchial in 11 cases (7.33 per cent of 150) 8.25 per cent of 133. The second aortic intercostal in 133 cases supplies intercostal spaces from 3 to 5 and the fourth space is more frequently supplied by this segmental artery. Only 1 of the 11 combined intercostal vessels supplies more than 1 interspace.

A third aortic intercostal artery is in bronchial combination in 2 instances (1.33 per cent of 150) 1.5 per cent of 133. In 1 case a single right bronchial is involved in the second and inferior right bronchial arises with the third aortic intercostal while the corresponding superior bronchial duplicates the relationship with the first aortic intercostal. Ruysch in his *Responsio* (1721) illustrated a common bronchial trunk arising from the right third

In 22 cadavers (14.7 per cent) one or more bronchial arteries arises from the arch of the aorta. In a single instance a left bronchial artery emerges from the anterosuperior surface of the arch immediately caudal to the roots of the innominate and left common carotid arteries and courses anterior to the trachea to reach its corresponding bronchus. In the 21 remaining cases the artery arises from some portion of the concavity of the arch cranial to the level of the first aortic intercostal vessels. In 15 (10 per cent) of these a single vessel passes to the left bronchus in 4 (2.7 per cent) a common stem provides arteries to right and left bronchi and in 2 specimens (1.3 per cent) a single right bronchial artery occurs. In only 1 case is the entire bronchial arterial supply derived solely from the aortic arch (cranial to the highest aortic intercostal) one of the 4 specimens with a common stem for both lungs arising from the concavity of the arch contributes one right and two left bronchial arteries to corresponding bronchi. In the specimen described by Boyden (1945) a single common artery arising from the inferior surface of the aortic arch bifurcated to supply both lungs.

In 3 instances (2 per cent) anomalous bronchial arteries are found to arise from a subclavian trunk. In 1 of these the aberrant vessel takes origin from the right subclavian and passes to the right superior lobar bronchus (Fig. 1 Type IX) in a second it is represented by a common stem which derived from the base of the left subclavian anteromedial to the internal mammary provides branches to right and left superior lobar bronchi in the third case a single artery arises from the left subclavian and passes to the corresponding superior lobar bronchus (Fig. 5). In each instance the arteries of subclavian origin are supplementary to one or more bronchial arteries of aortic origin. In Haller's classical case a common stem arose from the right subclavian and bifurcated to supply both lungs. In Quain's (1844) equally renowned specimen two common trunks arose from anomalous sites, from the internal mammary on the right side to provide branches to the anterior aspect of each bronchus, and from the superior intercostal on the left thereafter coursing dorsal to the subclavian artery to supply branches to the pos-

terior aspect of both bronchi. In the current series no specimen occurs in which major bronchial arteries are derived from the costovertebral trunk inferior thyroid or the internal mammary arteries although small anastomotic twigs between these vessels are frequently seen (see hereinafter).

Relation of origins to vertebral levels. Although the aortic origins of bronchial arteries range from the third to the eighth thoracic vertebral levels, nearly half of the arteries (right, 48.4 per cent left, 46.9 per cent) are related to the sixth segment and one-third (right, 34.4 per cent left, 33 per cent) to the fifth segment (see Tables IVA and IVB wherein the vertebral levels are tabulated by cases and by arteries, respectively). The remainder arise above and below the vertebral area just described with the greater degree of variation depending upon the total number of bronchial arteries in any particular specimen. The key vertebral levels in relation to the exposed mediastinal viscera are shown in Figure 6.

Considering all bronchial arteries of aortic origin as related to vertebral bodies, the following may be presented: origin opposite a single vertebral level in 57 cases (38 per cent), opposite two adjacent levels in 85 cases (56.6 per cent) opposite three adjacent levels in only 8 specimens (5.3 per cent). In 55 cases (36.7 per cent) the left bronchial arteries are opposite T5 and T6 as a unit in 26 cases (17.3 per cent) opposite T5 alone, and in 25 cases (16.7 per cent) opposite T6 alone. Thus, in 106 of 150 bodies (70.7 per cent) all left bronchial arteries of aortic origin emerge from a segment limited by the cranial margin of T5 and the caudal margin of T6.

*Whereas the width of the thoracic vertebral bodies gradually increases from above downward, there is relatively little difference in widths of bodies between T5 and T6. Variation will occur of course in relation to total body length and in the degree of spinal deformity. In determining thoracic levels in relation to sites of origins of bronchial arteries, the intervertebral discs are not considered, but included with adjacent vertebral bodies for per cent of record.

T = and the reader is the orientation of bronchial artery points of origin in reference to vertebral levels, the following vascular structures are commonly encountered opposite these topographic segments: (3) aorta; (4) T1—highest part of aortic arch, about 5 cm. caudad of jugular notch; T4—bifurcation of trachea; second part of aortic arch, beginning of thoracic aorta; T5—base of heart (cranialmost portion); T6—commencement of aorta and pulmonary artery; end of superior vena cava, distal right diaphragmatic function centrally.

The topographical relations on the right side are somewhat different, because of the association of the bronchial with intercostal arteries. In 57 cases (38 per cent) in which the bronchial arteries are not associated with intercostals the right bronchials arise opposite single vertebral levels T6 in 26 cases (17.3 per cent) T5 in 18 cases (12 per cent) T7 in 4 cases (2.7 per cent) and T4 in 3 cases (2 per cent). Right bronchial arteries unassociated with intercostals arise from the aorta at a slightly lower level than those on the left side. This circumstance is owing in part to the occurrence of the intercostobronchial trunk on the right which generally arises at the same level as the left superior bronchial artery.

On the basis of vertebral level of origin considered by arteries 260 left bronchial vessels (of an overall total of 267) arise from the descending aorta or from the aortic arch (Table IVB). Almost half of the left arteries emerge from the aorta opposite the sixth thoracic vertebral level. The range of origins extends between extremes of T3 and T8 with the majority of left bronchial arteries (80 per cent) arising opposite the combined levels of T5 and T6.

In 57 cases with right bronchial arteries arising from the aorta independent of intercostal arteries there is a total of 64 vessels the remaining 141 arteries (in 93 cases) take origin in common with intercostals or are derived from the subclavian (2 cases 2 vessels). As with the left side approximately half (31 of 64 arteries 48.4 per cent) of the independent right bronchial arteries arise from the aorta opposite T6 and 82.8 per cent opposite the combined levels of T5 and T6. The range however is more restricted than on the left side extending between T4 and T7. Thus 8 out of 10 right and left independent aortic bronchial arteries originate opposite the bodies of the fifth and sixth thoracic vertebrae.

Course. The right bronchial artery is more constant than the left in origin course and distribution. A single right artery arises from the corresponding lateral aspect of the aorta, or from its dorsolateral surface when in combination with an intercostal. In the latter type (88.67 per cent) the artery courses cranialward to insinuate itself between the azygos

vein and the vertebral bodies. At or near this site the intercostobronchial bifurcates to provide an aortic intercostal (Table II) to the appropriate intercostal space and a definitive bronchial artery which leaves the parent stem at a variable angle to course obliquely caudalward and anteriorly beneath the arch of the azygos vein on the way to the right bronchus (Fig. 4). The right bronchial artery is more frequently associated with the highest aortic intercostal when it is not it arises at too low a level to pass beneath the azygos arch. In a specimen with two right bronchial arteries each of which arises in common with an intercostal the right superior artery passes beneath the arch the inferior one does not (Fig. 3). Since the artery lies in close relationship to the trachea and esophagus it provides numerous twigs of supply to each (see hereinafter).

When a right bronchial artery arises from the aorta unassociated with an intercostal its course to the bronchus is usually more direct. From its origin on the anterolateral lateral or posterolateral aspect of the aorta the artery passes anteriorly and cranialward or anteriorly and lateralward to the right of the esophagus to reach the bronchus. Its relationship to the bronchus is similar to that of the branch derived from an intercostobronchial trunk although it is generally found in a more caudal position on the posterior surface of the bronchus.

An inferior right bronchial artery when present (33.3 per cent of cases) arises either from the corresponding lateral or anterior surface of the thoracic aorta. It may course to the right of and dorsal to or to the left of and anterior to the esophagus on its way to the right inferior lower bronchus¹⁰ (hyparterial bronchus of Aebly). Vessels of anterior origin may course superiorly to loop about the cranial aspect of the left main bronchus and then pass inferiorly inclining toward the right, on

¹⁰The nomenclature of Jackson and Heber (1941) is employed: (a) superior lobar bronchus (right upper lobar bronchus and left upper lobar bronchus (bronchus [super] of Ewart eparterial bronchus of Aebly), (b) middle lobar bronchus (right middle or cardiac bronchus of Ewart, first hyparterial ventral bronchus of Aebly), (c) inferior lobar bronchus (right and left lower lobar bronchus of Ewart, hyparterial bronchus of Aebly).

Subsequent reference to the distribution of the middle or inferior bronchial arteries to the inferior lobar bronchus refers, on the right side, to the common stem for definitive middle and inferior lobe bronchi derived from the bifurcation of the main bronchus; this is the bronchus intermedius of Ewart.

the anterior surface of the tracheal bifurcation branches are supplied to adjacent lymph nodes en route and the artery continues along the caudal border of the right main bronchus.

In 11 33 per cent of the bodies (17 of 150) one or more right bronchial arteries wind to the left and pass anterior to the esophagus in transit to the right main bronchus. In 13 of the cases the right bronchial is derived from a common stem with a left bronchial artery, and in 4 cases the right bronchial artery arises independently from the aorta. In 8 7 per cent of bodies (13 of 150) a right bronchial artery passes anterior to the trachea or tracheal bifurcation to reach the right main bronchus. In 8 of the cases the right bronchial arises in common with a left bronchial artery, and in 5 cases it has an independent aortic origin. One right bronchial artery from a common stem passes through the tracheal crotch to the anterior surface of the right bronchus resembling in its course the bronchial artery of left subclavian origin described by Schneider (1934). In other right bronchial artery of independent aortic origin passes anterior to the left main bronchus and bifurcation then turns posteriorly through the crotch to reach the dorsal aspect of the right main bronchus.

In 39 cases (26 per cent) in which one or more left bronchial arteries arise in common with a right bronchial 21 (14 per cent) possess a common stem which courses to the left dorsal to the esophagus, and bifurcates at its lateral margin (Fig. 2). The left bronchial artery then continues directly to the left main bronchus, while the right artery passes anterior to the esophagus or ascends to loop over the left bronchus and courses on the anterior aspect of the tracheal bifurcation in the manner previously described.

In the case having four right bronchial arteries (Fig. 1 Type IX) a strikingly anomalous vessel arises from the right subclavian immediately proximal to the origin of the corresponding internal mammary artery. It descends to the right of the trachea and dorsal to the superior vena cava after crossing anterior to the azygos vein it enters the pulmonary hilum along the cranial border of the superior lobar bronchus (eparterial bronchus of Aebly).

The bronchial arteries to the left lung follow a more direct and simpler course. Since most of them arise from the anterior surface of the aorta immediately behind the left main bronchus they must pass anteriorly to meet the bronchus. In one third of cases (34 7 per cent) one or more left bronchial arteries arise from the right anterolateral or lateral aspect of the aorta and pass dorsal to the esophagus to reach the left bronchus. In the single instance in which the left bronchial artery courses anterior to the esophagus it is a derivative of a common stem with a right bronchial artery. In another case a left bronchial artery emerges from the right dorsolateral aspect of the aorta at the level of the second right aortic intercostal and winds ventral to the aorta to reach the left bronchus. A left bronchial artery passes anterior to the trachea proximal to the bifurcation. In 3 cases (2 per cent) and its anterior course is restricted to that aspect of the left bronchus alone in 3 specimens (5 33 per cent). In 2 instances of the latter pattern both superior and inferior left bronchial arteries have a similar course, providing a total of 10 arteries so located (2 67 per cent of total left arteries).

Major anastomotic vessels are found connecting adjacent left bronchial arteries in 4 cases (2 67 per cent) (1) between superior and inferior bronchials (2) between superior and middle (3) between middle and inferior and (4) between the superior and second of 4 arteries. These anastomoses extend either obliquely or vertically across the posterior aspect of the main bronchus. In 3 cases (2 per cent) a major anastomosis extends transversely to connect a right and left bronchial artery, and in 1 of these the anastomotic channel courses anterior to the esophagus. Major anastomoses between inferior bronchial and primary aortic esophageal arteries are found in 47 cases (31 3 per cent) but smaller gross anastomoses between these two classes of vessels occur in every case studied.

In 8 cases (5 33 per cent) arteries to the inferior lobar bronchi arise cranial to the origins of superior lobar supply. In 5 of these the artery courses to the right lung in 1 to the left and in 2 a common stem bifurcates to supply both lungs.

The definitive bronchial artery seldom occupies the midportion of the dorsal membrane of the main bronchus although commonly it is said to do so. The superior bronchial arteries pass cranialward to reach the main bronchi on the right side at the site of bifurcation on the left side approximately 1 centimeter distal to the bifurcation corresponding to the width of the esophagus. It then tends to follow the posterosuperior margin of the cartilaginous bronchus at the site of attachment to the dorsal membrane to the superior lobar bronchus. Less frequently the entire course is along the anterior surface of the bronchus. Prominent twigs are often sent to the anterior aspect of the bronchus even when the main vessel is more dorsally placed.

The inferior bronchial arteries tend to pursue a transverse course across the pericardium in the interval caudal to the tracheal bifurcation to reach the posterosuperior or postero-inferior aspect of the inferior lobar bronchus. In their course they provide descending anastomotic rami to the esophagus and posterior mediastinal fascia. In many cases the artery follows the most dependent surface of the bronchus. Arterial rami to the anterior aspect of the inferior lobar bronchus are seen less frequently than are those of superior bronchial origin to the corresponding bronchus.

Terminally in the region of the hilum the single right bronchial artery bifurcates to supply superior and inferior lobar bronchi and their secondary subdivisions by multiple branches. In the presence of multiple arteries the superior bronchial follows the cranial border of the superior lobar bronchus while the inferior bronchial courses along the caudal or postero-inferior border of the inferior lobar bronchus. A middle bronchial when present, tends to subdivide at the main bronchial bifurcation and to send rami to both superior and inferior lobar bronchi. Immediately distal to the bifurcation of the main bronchus each arterial ramus usually assumes a more central position on the posterior membranous wall. Peribronchial arborization and anastomoses are common in the region of the hilum. Hovelacque describes a case of anastomosis between a left bronchial artery of aortic origin with the left inferior pulmonary vein.

Esophageal and other branches. Textbooks categorically describe the esophageal arterial supply as being derived in part from the bronchial arteries but little specific information concerning the overall vascular pattern for the esophagus is available.¹¹

In the present series it is constantly observed that the predominant blood supply of the middle third of the esophagus is derived from the bronchial arteries (Figs. 4, 5 and 7). Anastomoses between the bronchial and aortic esophageal branches are regularly present in 31.3 per cent of cases major anastomoses occur between inferior bronchial and esophageal arteries. Right bronchial arteries from intercostobronchial trunks always supply the dorsal aspect of the distal portion of the trachea and the adjacent segment of esophagus. Right inferior aortic arteries when present supply the esophagus liberally this would be expected from the dorsal transeophageal course of the vessel.

One or more constant large esophageal arteries arise from the anterior aspect of the thoracic aorta opposite T8 to T10. In 3 cases primary aortic esophageal arteries contribute branches of the caliber of bronchial arteries to the lower lobe of the lung (left 2 right 1) entering the parenchyma through the pulmonary ligament in its middle and inferior thirds.¹² Quain (citing Turner) described the frequent occurrence of small arteries extending laterally from the aorta to the lung between the folds of the pulmonary ligament and McCotter observed these vessels frequently. They are a prominent feature in the arterial supply of the dog's lung (Berry, Brailsford, and Daly).

In approximately 10 per cent of cadavers large pericardial arteries are derived from the bronchial arteries. These are more frequently associated with a right bronchial artery which passes superior to the left main bronchus and with right inferior bronchial arteries.

¹¹According to Cunningham (1937) its arteries consist of branches derived in the neck from the inferior thyroid, in the thorax from the bronchial arteries and thoracic aorta, and in the abdomen from the left gastric artery and from the inferior phrenic.

¹²The contents of the pulmonary ligaments were studied in only a few cases, so these data are not indicative of the true incidence of pulmonary arterial supply from primary aortic esophageal arteries. This information will be provided in an extensive study of the esophageal arterial supply currently in progress in this laboratory.

The paratracheal and bronchial lymph nodes receive an abundant supply from the bronchial arteries. Often the artery traverses a node en route to the bronchus. While in the current series no major bronchial artery is observed to arise directly from an internal mammary artery anastomoses effected by small twigs occur constantly between the superior right bronchial and the corresponding internal mammary arteries. These twigs extend either longitudinally or obliquely dorsal to the superior vena cava and lateral margin of the trachea.

Anastomosis is effected between superior bronchial arteries and the right subclavian and superior intercostal arteries, the minute rami derived from the network of vessels then supplying paratracheal and proximal bronchial lymph nodes.

Indirect anastomosis between the right bronchial of intercostobronchial derivation and the superior intercostal and subclavian is also established through the first aortic intercostal which often arises in common with the definitive bronchial artery.

The potential anastomotic relationship between bronchial and associated mediastinal arteries and the coronary arteries was described by Hudson, Moritz, Wearn (1932). By injection technique these authors demonstrated widespread anastomoses of auricular branches and the coronary branches to the pericardial fat with pericardicophrenic branches of the internal mammary arteries and with the anterior mediastinal pericardial, bronchial superior and inferior phrenics in intercostal and esophageal branches of the aorta. Gross anastomoses between the intercostal internal mammary esophageal and bronchial arteries were also demonstrated in the dog as lung by Berry, Brailsford, and Daly and by Horine and Warner (1932).

The vagus and associated pulmonary nerves receive minute rami from the bronchial arteries (Fig 7) as well as from adjacent intercostal, esophageal and mediastinal vessels.

Situs inversus viscerum. One cadaver (not included in the tabulations) reveals a complete situs inversus viscerum. Its bronchial artery pattern with one left and two right vessels is the mirror image of Type I. The left

artery arises in common with a first left intercostal and the right inferior bronchial from the lateral aspect of the aorta. Neither of these arrangements occurs per se in the regular series. The levels of origin are slightly lower than those usually seen, the right arteries being found opposite T6 and T7. The left intercostobronchial artery provides an intercostal branch to supply the first, second and third intercostal spaces.

CONCLUSIONS AND SUMMARY

The origin, course and distribution of the bronchial arteries are described for a series of 150 cadavers. The specimens are catalogued on the basis of types (I to IX) in the order of decreasing frequency of occurrence, and subdivided on the bases of arterial origin. Type I, two left and one right arteries, in 40.67 per cent. Type II, one left and one right, in 21.33 per cent. and Type III, two arteries to each side in 20.67 per cent. comprise 82.67 per cent of all patterns. Variations in number including 4 arteries to a side (2 cases) and a total of 5 bronchial arteries (6 cases) are observed.

The aortic sites of origin of right bronchial arteries differ markedly from those of the left side not only in position but in relation to parietal vessels. These bronchial vessels arise on the right anterolateral, lateral, or posterolateral surface of the aorta and in 83.7 per cent of cases in common with an aortic intercostal artery. The right 1st aortic intercostal participates in the common intercostobronchial stem in 78 per cent, the 2nd aortic intercostal in 7.33 per cent, and the 3rd aortic intercostal in 1.33 per cent. Left bronchial arteries arise from the anterior surface of the aorta or from the arch less commonly they emerge from the right lateral or posterolateral aspect and only rarely from the left surface. In only 6 cases (4 per cent) does a left bronchial arise in common with an intercostal artery, the latter vessel is invariably a right intercostal. Except in the rare case of situs inversus viscerum bronchial arteries of either side have no relationship with left intercostal vessels.

In 74 per cent of cadavers bronchial arteries arise independently of each other in

THE USE OF SULFADIAZINE AS A PREOPERATIVE AND POSTOPERATIVE MEASURE IN HYPERTHYROIDISM

JOHN H. MULHOLLAND M.D., F.A.C.S., JOHN A. LAWLER, M.D., F.A.C.S., and
ELAINE P. RALLI M.D., F.A.C.P., New York, New York

THE management of the patient with thyroid disease in a large municipal hospital presents certain problems because of the size of the wards and the consequent lack of privacy and quiet. This condition constitutes a very vital hazard to the patient with hyperthyroidism to whom stimuli of almost any kind are particularly upsetting. Since 1929 the medical and surgical services of the Third (New York University) Division Bellevue Hospital have collaborated in the care of these patients; one member of each staff being primarily responsible in co-operation with the resident physicians of each service for the handling of the patient. Therapy consisted of a high caloric diet during the preoperative period and Lugol's solution 20 to 30 drops daily. This treatment was continued until the patient showed a decrease in the degree of hyperthyroidism as evidenced by gain in weight fall in the basal metabolic rate and slowing of the heart rate. From 1909 to 1941 thyroidectomies were performed on a total of 432 patients. Twenty patients died postoperatively either in thyroid crisis within 48 hours after operation or as a result of infection associated with thyroid crises. Analyses of the deaths showed that (1) in several of the patients there had been a tendency to some elevation of temperature in the preoperative period (2) immediately after operation there was a sharp rise in temperature and heart rate (3) signs of pneumonia usually developed if the patient survived for more than 24 hours and (4) on postmortem examination there was evidence of lobular or lobar pneumonia. Infection has often been reported as a factor in precipitating thyroid crises (2) and the findings in our patients seemed to support this observation. Therefore in September 1941 as a measure intended to prevent infection sulfonamide therapy was instituted following operation whenever the temperature rose to 101 degrees. In the first cases sulfathiazole was given but sulfadiazine soon became available and has been used since. Sulfonamide therapy was so satisfactory in controlling the temperature and any associated infection that it was decided to give the drug before operation in an effort to prevent postoperative infection. Each patient received 8 grams of sulfadiazine by mouth in divided doses in the 24 hour period before operation. The sulfadiazine was continued after operation 4 grams daily for to 4 days. The administration of sulfadiazine has constituted the only significant change in the management of patients since the fall of 1941. This method of therapy was begun about the time that Mackenzie and associates (November 1941) (6) published their original report on the effect of sulfaguanidine on the thyroid glands in rats. In 1942 and again in 1943 the Mackenzies (4, 5) and Astwood demonstrated the goiterogenic activity of additional sulfonamides and of thiourea. It seemed possible on the basis of their reports that by the use of sulfadiazine dual effects were being obtained: i.e. antithyroid and anti-infective which perhaps accounted for the results.

RESULTS

This method of therapy has now been used on a total of 75 patients of whom 54 had severe hyperthyroidism (Table I). In several patients the operation was done in 2 stages because of the degree of thyrotoxicosis so that a total of 85 operations were done. Since its use no deaths have occurred. It may be argued that the number of cases is not large but in a similar number of patients (Table II) operated on before this regimen there were 4 deaths and many of the patients had a stormy post-

From The Third (New York University) Medical and Surgical Divisions of Bellevue Hospital and the New York University College of Medicine, New York, N.Y.

Chart Case 493. 24 year old female Basal metabolic rate prior to administration of Lugol's solution +70 per cent prior to operation and after 78 days of Lugol's solution +30 per cent. One lobe of the thyroid gland was removed at the first operation. On the first day following operation the temperature rose 1 degree and the pulse continued to be rapid. The patient became restless and very difficult to quiet. 5 gr thiazole 30 cc by mouth. The temperature rose 1 degree the pulse 40 per minute and then both pulse and temperature began to fall. The pulse rate remained low for several days and then fell to normal limits. The drug was discontinued after the 4th postoperative day.

operative course Sulfadiazine has also been used in the treatment of thyroid crises occurring before operation and has controlled the condition rapidly as is illustrated in Case 490. The advantages of sulfadiazine are that it has relatively little toxicity that it can be given intravenously and that the effect in the patient in thyroid crisis is rapid.

Effect of sulfonamide therapy in the postoperative course and in thyroid crises The course in 6 patients has been charted to illustrate the effects of sulfonamide therapy. In 3 patients (Cases 483, 497 and 516 Charts 1 to 3) the drug was only given postoperatively when the temperature and heart rate had begun to rise. Case 483 (Chart 1) was a 24 year old female with severe hyperthyroidism. Her response to Lugol's solution had not been satisfactory and during the 78 days of preoperative care in the hospital, the basal metabolic rate had varied from +75 to +54 per cent. No sulfonamide was given preoperatively. Following the first operation at which one lobe of the thyroid was removed the temperature rose to

TABLE I—SUMMARY OF 85 OPERATIONS ON 15 PATIENTS TREATED WITH SULFADIAZINE

Number of females	8
Number of males	7
Age range in years	20 to 32
Number of patients with hyperthyroidism	8
Average B.M.R. of the hyperthyroid patients	
After Lugol's solution and before operation	+58 per cent
Range of B.M.R. after Lugol's	+31 to +60 per cent

TABLE II—SUMMARY OF 81 OPERATIONS ON 15 PATIENTS TREATED PRIOR TO USE OF SULFADIAZINE THERAPY

Number of females	6
Number of males	14
Age range	22 to 30 years
Average B.M.R. of preoperative hyperthyroid patients	
After Lugol's solution and before operation	+50 per cent
Range of B.M.R. after Lugol's	+34 to +60 per cent

Deaths in This Group

Preoperative B.M.R.	+32	+12	+44	+19
Day of death after operation	1st	7th	8th	1st

Second stage operation.

103 degrees, the pulse rate to 140 per minute, and the restlessness characteristic of thyroid crises was manifested. Fluids were given intravenously and in addition sulfadiazine was administered. The temperature and pulse declined the patient became quieter and within 12 hours intravenous administration of fluids was discontinued. The severe degree of hyperthyroidism was reflected in the microscopic section of the lobe removed at the first operation which showed acini of varied size which only in certain areas contained poorly staining colloid. The epithelium appeared heaped up with buds in the acini. In areas the epithelial hyperplasia was so great that no definite acinar structure was seen.

CASE 497 (Chart 2) was a 33 year old male. Preoperatively no sulfadiazine was given. The basal metabolic rate 2 days before operation was +38 per cent. The temperature began to rise during the evening of the day of operation. Sulfadiazine was begun (2.5 grams intravenously) and was continued for 3½ days. The temperature was readily controlled and the patient made an uneventful recovery.

CASE 516 (Chart 3) a 26 year old female, had had a complicated preoperative course due to a respiratory infection and an ulcer of the cornea. The preoperative period was prolonged and with administration of Lugol's solution the basal metabolic rate had only decreased from +52 to +42 per cent. No sulfadiazine was given preoperatively. On the day fol-

Chart 2. Case 497, a 33 year old male. The patient had had a previous admissions and had refused operation. He was carried on Lugol's solution for 5 months. His basal metabolic rate just prior to operation was +43 per cent. At this first operation the right lobe of the thyroid was removed. The pulse rate rose during the operation and when the temperature rose to 101 degrees on the night of operation sulfadiazine was begun. The first dose was given intravenously along with an infusion. The pulse rate remained elevated for several days but the temperature was controlled by the 2nd day and the patient made an uneventful recovery.

Chart 3. Case 516, a 26 year old female. Basal metabolic rate prior to administration of Lugol's solution +52 per cent prior to operation +42 per cent. The preoperative course was prolonged due to a respiratory infection which was followed by corneal ulcers. No sulfadiazine was given preoperatively. On the first postoperative day the temperature rose to 101.8 degrees, the pulse to 140, and the patient became restless and apprehensive. Sulfadiazine was begun and by the 3rd postoperative day both the temperature and pulse were controlled.

Following operation the temperature rose to 101.8 degrees and the heart rate was 140 per minute. Sulfadiazine was begun on the afternoon of that day and as is shown in the chart both the heart rate and the temperature began to drop and the drug was discontinued on the third day as the patient was objectively and subjectively greatly improved.

Cases 498, 524 and 547 (Charts 4 to 6) received sulfadiazine in the 24 hours before operation and it was continued after operation as is indicated. Case 498 (Chart 4) was a 21 year old female whose basal metabolic rate had fallen from +32 to +10 per cent. The postoperative course was exceptionally smooth the temperature rising on only 1 occasion to 101.4 degrees. Case 524 was a 39 year old colored female with diabetes mellitus as well as hyperthyroidism. The patient had been receiving Lugol's solution as an out patient for 5 months. When she consented to operation she was hospitalized and before operation the basal metabolic rate was +13 per cent. There was a rise in temperature to 102 degrees on the first day after operation but this fell on the same day to 100.8 degrees and the course from then on was uneventful. Case 547 (Chart 6) was a 37 year old colored female. This patient was apprehensive, nervous, and restless during the preoperative period. With administration of Lugol's solution the basal metabolic rate fell from +57 to +35 per cent. The heart rate was elevated daily ranging from 98 to 130

per minute. Sulfadiazine was given preoperatively and although the patient continued to have a rapid heart rate for the first 5 days after operation and the temperature rose on the 1st and 2nd day to 102.4 degrees, her postoperative course was well controlled.

The effect of sulfadiazine in a patient who developed thyroid crisis on 3 occasions is demonstrated in Chart 7. This was Case 490, a 46 year old colored male patient whose entire course was unstable and whose hyperthyroidism was complicated by congestive heart failure. The operation was done in 2 stages. At the first operation the right lobe of the thyroid was removed. Postoperatively the temperature rose to 104.2 degrees, the pulse to 170 per minute. Sulfadiazine was given intravenously then by mouth and continued for 9 days. Within 24 hours the pulse rate had decreased to 136 per minute and the temperature to 101.4 degrees. The patient was readmitted 5 months later for the second stage operation. During the period of preparation for thyroidectomy the patient appeared to be developing thyroid crisis the temperature rising to 104.4 degrees and the pulse rate to 168 per minute. He received sulfadiazine and sodium iodide intravenously with a prompt remission of the symptoms. He was operated on 16 days later and through error no sulfadiazine was given preoperatively. On the day after operation the temperature rose to 105.6 degrees. Sulfadiazine was then given intravenously and both temperature and pulse rate fell rapidly the remainder of the postoperative course was uncomplicated.

Chart 4. Case 408, 37 year old female. Basal metabolic rat prior to administration of Lugol's solution +38 per cent, after its administration +80 per cent. Preoperative period was 4 weeks. Sulfadiazine was given during the 24 hours prior to operation and was continued for 4 days following operation. The postoperative course was uncomplicated and the patient was discharged from the hospital on the 8th postoperative day.

Chart 5. Case 544, a 30 year old colored female with severe diabetes mellitus. Prior to the administration of Lugol's solution the basal metabolic rat was +45 per cent. She was treated with Lugol's solution in the clinic for 4 months and was then sent into the hospital for operation. The basal metabolic rat prior to operation was +38 per cent. Sulfadiazine was given in the 24 hours before operation and was continued until the 4th postoperative day. The temperature rose on the afternoon of the 1st postoperative day but aside from this the postoperative course was uneventful.

Chart 6. Case 547, 37 year old colored female. This patient was nervous and apprehensive and no satisfactory basal test could be done prior to the administration of Lugol's solution. After Lugol's solution had been given for 60 days the basal metabolic rat was +45 per cent. Sulfadiazine was given in the 24 hours prior to operation and right hemithyroidectomy was done. The pulse rate remained elevated for 4 days and the temperature rose on the 1st and 2nd postoperative days to 103 degrees. The patient, however, was quiet and showed no signs of thyroid crises.

As a comparison the characteristic reaction of uncontrolled thyroid crises occurring postoperatively is illustrated in Chart 8. These 3 patients received the therapeutic measures employed prior to the discovery of antithyroid drugs, i.e. infusions, sodium iodide sedation, and iced enemas to reduce the temperature with no effect—both patients died. This severe type of reaction accompanied by a rapid rise in temperature and pulse rate has been controlled in the patients receiving sulfadiazine before and after operation.

Microscopic appearance of the glands. Microscopic sections of all glands removed at operation were examined. We are indebted to Doctor John Hall of the Department of Pathology for his opinion and diagnosis of the sections. Unfortunately on the basis of the microscopic appearance of the glands it was not possible to evaluate the goiterogenic effect of the sulfadiazine administered in the 24 hours before operation. This is not surprising as in patients with severe hyperthyroidism the involution resulting from administration of Lugol's solution is irregular and areas of com-

siderable hyperplasia are usually present. The general impression of the microscopic sections of the glands of the patients in this series was that they were still hyperplastic but that there was also evidence of the involution associated with iodine administration. The acini varied in size, some containing light and others dark or pink staining colloid. The epithelium lining the acini varied from plump cuboidal cells to layers of columnar cells in the larger acini. Many acini contained papillary epithelial processes which extended into the lumen. Some few collections of lymphocytes were scattered throughout the interstitial tissue. In Figure 1 are shown microscopic sections of the thyroid glands removed from Cases 524 and 497 (second operation). Both patients received 8 grams of sulfadiazine in the 24 hours prior to operation. In Figure 2 are microscopic sections from Cases 483 and 497 (first stage operation). Neither of the patients received sulfadiazine preoperatively. All of the sections show hyperplasia of the thyroid tissue with areas of colloid deposition. It is obviously difficult to judge to what extent the hyperplasia might have been influenced by the preoperative administration of sulfadiazine. Even in Case 497 in which the patient received sulfadiazine before the second stage thyroidectomy (Fig. 1) but received none before the first stage it would be difficult to evaluate the antithyroid effect of the drug.

The state of the thyroid gland at operation in the patients receiving sulfadiazine preoperatively provided no unusual technical difficulties. Bleeding was not a complication nor was the gland friable or easily torn.

DISCUSSION

Hyperemia and enlargement of the thyroid gland have been shown to follow the administration of the sulfonamides as well as of thiouracil (4, 5, 6). The Mackenzies (5, 6) reported that sulfaguanidine, sulfadiazine and sulfapyridine were effective in this respect. They noted that the administration of iodine conferred no protective action on the thyroids of animals fed sulfaguanidine. In fact the condition of the thyroid gland both as to enlargement and histologic changes seemed to be aggravated by the administration of

Chart 7. Case 490, a 46 year old colored male was admitted in congestive heart failure complicating hyperthyroidism. The basal metabolic rate prior to operation after 50 days of administration of Lugol's solution was +25 per cent. A right lobectomy was done at 11. First operation. The temperature and pulse rose and the patient developed the characteristic signs of thyroid crisis. Sulfadiazine was begun intravenously and continued orally. The signs of crisis abated and the patient improved. The basal metabolic rate at the time of discharge 17 days after operation was +5 per cent. The patient returned for the second stage operation 3½ months later. He developed thyroid crises during the preoperative period and this was controlled by the administration of sulfadiazine. Due to an error he received no sulfadiazine preoperatively and on the first postoperative day he again developed the signs of crisis and again he responded to the administration of sulfadiazine. The patient received either Lugol's solution or a cumulative dose of iodine during the entire time.

Chart 4. Case 498. 37 year old female. Basal metabolic rate prior to administration of Lugol's solution +3 per cent, after its administration +20 per cent. Preoperative period was 7 weeks. Sulfadiazine was given during the 24 hours prior to operation and was continued for 5 days following operation. The postoperative course was uncomplicated and the patient was discharged from the hospital on the 8th postoperative day.

Chart 5. Case 524. 39 year old colored female with severe diabetes mellitus. Prior to its administration Lugol's solution the basal metabolic rate was +45 per cent. She was treated with Lugol's solution in the clinic for months and was then sent into the hospital for operation. The basal metabolic rate prior to operation was +38 per cent. Sulfadiazine was given in the 24 hours before operation and was continued until the 4th postoperative day. The temperature rose on the afternoon of the 4th postoperative day but aside from this the postoperative course was uneventful.

Chart 6. Case 547. 33 year old colored female. This patient was nervous and apprehensive and no satisfactory basal test could be done prior to the administration of Lugol's solution. After Lugol's solution had been given for 60 days the basal metabolic rate was +45 per cent. Sulfadiazine was given in the 24 hours prior to operation and right hemithyroidectomy was done. The pulse rate remained elevated for 4 days and the temperature rose on the 1st and 2nd postoperative days to 101 degrees. The patient however was quiet and showed no signs of thyroid crises.

As a comparison the characteristic reaction of uncontrolled thyroid crises occurring postoperatively is illustrated in Chart 8. These 2 patients received the therapeutic measures employed prior to the discovery of antithyroid drugs, i.e. infusions, sodium iodide sedation, and iced enemas to reduce the temperature, with no effect—both patients died. This severe type of reaction accompanied by a rapid rise in temperature and pulse rate has been controlled in the patients receiving sulfadiazine before and after operation.

The state of the thyroid gland at operation in the patients receiving sulfadiazine preoperatively provided no unusual technical difficulties. Bleeding was not a complication nor was the gland friable or easily torn.

DISCUSSION

Hyperemia and enlargement of the thyroid gland have been shown to follow the administration of the sulfonamides as well as of thiouracil (4, 5, 6). The Mackenzies (5, 6) reported that sulfaguanidine, sulfadiazine and sulfapyridine were effective in this respect. They noted that the administration of iodine conferred no protective action on the thyroids of animals fed sulfaguanidine. In fact the condition of the thyroid gland both as to enlargement and histologic changes seemed to be aggravated by the administration of

Chart 7. Case 490, a 41-year-old female, male, admitted in congestive heart failure complicating hyperthyroidism. The basal metabolic rate preoperatively after 30 days of administration of Lugol's solution was +25 per cent. A right lobectomy was done at the first operation. The temperature and pulse rose and the patient developed the characteristic signs of thyroid crisis. The crisis was begun intravenously and continued orally. The signs of crisis abated and the patient improved. The basal metabolic rate at the time of discharge 17 days after operation was +5 per cent. The patient returned for the second operation 245 months later. A left lobectomy was done during the preoperative period and this was controlled by the administration of sulfadiazine. Due to an error, the patient received no sulfadiazine preoperatively and on the first operative day he again developed the signs of thyroid crisis. The patient responded to the administration of sulfadiazine. The patient received either Lugol's solution or Lugol's Iodine during the entire time.

Chart 8 Course in 2 patients who developed thyroid crises following operation and died prior to institution of sulfadiazine therapy. Left, Case 64, a 51 year old female. Basal metabolic rate prior to administration of Lugol's solution +37 per cent, after Lugol's and prior to operation +3 per cent. The pulse rate increased during the operation and remained elevated. The temperature rose on the first postoperative day and the patient became restless and apprehensive. The treatment consisted of transfusion, infusions, sedation and administration of Lugol's solution. She died on the 3rd postoperative day.

Right Case 397. 48 year old female. This was the second stage of the thyroidectomy. Basal metabolic rate on admission was +6 per cent, after preoperative preparation +51 per cent. The patient had been on Lugol's since the first operation. As the patient's heart rate was within normal limits and the temperature was never above 98.6 degrees, and this as the second stage operation, it was considered safe to proceed. Both the pulse and temperature rose precipitously following operation. The temperature fell on the first postoperative day but rose again. The pulse rate remained very rapid and the patient developed the restlessness and apprehension characteristic of thyroid crisis. She died on the 3rd postoperative day.

The uncontrolled reaction in these cases should be compared to the courses in Cases 483, 497 and 490, in which sulfadiazine was given when the temperature and pulse rate rose following operation.

iodine. Astwood in assaying the various sulfonamides in respect to their goiterogenic activity found that sulfadiazine was the most effective. Administration of the sulfonamides to rats was accompanied by hyperplasia of the thyroid and a lowering of the basal metabolic rate.

The exact mechanism by which the sulfonamides and the thioureas exert their goiterogenic effect has been the subject of some discussion. In a recent report Mackenzie (3) postulates that the action of the sulfonamides differs from that of the thioureas and that this difference is illustrated when sodium iodide is given in conjunction with thiouracil or sulfaguanidine. He observed that the response to thiouracil was affected in two ways by the addition of sodium iodide to the diet of the rat. Small amounts of iodide inhibited the thyroid enlargement produced by thiouracil but had

no effect on the hyperplasia. Larger amounts of iodide suppressed the hyperplastic change that usually accompanies the enlargement of the gland. However when sulfaguanidine and sodium iodide were given together "iodide neither reduced the size of the thyroid nor inhibited the degree of hyperplasia. On the contrary a high level of iodide actually potentiated the goiterogenic action of low levels of sulfaguanidine and increased the weight of the gland by 30 to 40 per cent. These observations are of particular interest to us as we administered either Lugol's solution or sodium iodide along with the sulfadiazine to the patients and found that this method of therapy reduced the incidence of severe postoperative reactions and controlled thyroid crises when it

According to the U.S.P. formula for Lugol's solution, it contains 2.6 per cent iodine, 5 per cent of which is free or elemental iodine and 7.6 per cent of which is present as iodide.

Fig. 1. Microscopic sections from the thyroid glands of Cases 524 and 497 (second operation). Both of the patients received 8 grams of sulfadiazine in the 24 hour period prior to operation. Left, Case 524 had been receiving Lugol's solution for 5 months prior to operation. The basal metabolic rate before operation was $+13$ per cent. There is pronounced hyperplasia of the gland and also evidence of some involution with colloid deposition. Right in Case 497 this is the section of the thyroid gland removed at the 2nd stage

of a 2 stage thyroidectomy. The patient received sulfadiazine prior to this operation. He had been receiving Lugol's solution since before the first operation a total period of 210 days. This section shows colloid deposition and also areas of remaining hyperplasia. The microscopic section from the gland removed at the first operation at which time no sulfadiazine was given, is shown in Figure 2. There does not seem to be any significant difference in the degree of hyperplasia or colloid deposition shown in these sections.

Fig. 2. Microscopic sections from the thyroid glands of Cases 483 and 497 (first stage operation). These patients did not receive sulfadiazine preoperatively. The sections show hyperplasia and areas of involution with colloid deposition. The basal metabolic rate in Case 483 left, prior to operation was $+34$ per cent, and in Case 497 right, it

was $+38$ per cent. The course in these 2 patients is shown in Charts 1 and 2. The microscopic section in Case 497 should be compared to the microscopic section from the gland of this same patient shown in Figure 1 as the latter was removed at the second operation prior to which the patient received sulfadiazine.

occurred either before or after operation. The question of a goiterogenic effect in the patients was impossible to evaluate satisfactorily on the basis of the microscopic appearance of the

gland. When the sulfadiazine was given before operation it was only for a period of 24 hours and it might well be questioned whether this period of time was sufficiently long to per

Chart 8 Course in patients who developed thyroid crises following operation and died prior to the institution of sulfadiazine therapy. Left, Case 164, 51 year old female. Basal metabolic rate prior to administration of Lugol's solution + 7 per cent, after Lugol's operation + 3 per cent. The pulse rate increased during the operation and remained elevated. The temperature rose on the first postoperative day and the patient became restless and apprehensive. The treatment consisted of transfusion, infusions, sedation and administration of Lugol's solution. She died on the 3rd postoperative day.

Right, Case 197, 48 year old female. This was the second stage of the thyroidectomy. Basal metabolic rate on admission was +6 per cent, after preoperative preparation +33 per cent. The patient had been on Lugol's since the first operation. As the patient's heart rate was within normal limits and the temperature was never above 38.6 degrees, and this was the second stage operation it was considered safe to proceed. Both the pulse and temperature rose precipitously following operation. The temperature fell on the first postoperative day but rose again. The pulse rate remained very rapid and the patient developed the restlessness and apprehension characteristic of thyroid crises. She died on the 3rd postoperative day.

The uncontrolled reaction in these cases should be compared to the courses in Cases 483, 497 and 499 in which sulfadiazine was given when the temperature and pulse rate rose following operation.

iodine. Astwood in assaying the various sulfonamides in respect to their goiterogenic activity found that sulfadiazine was the most effective. Administration of the sulfonamides to rats was accompanied by hyperplasia of the thyroid and a lowering of the basal metabolic rate.

The exact mechanism by which the sulfonamides and the thioureas exert their goiterogenic effect has been the subject of some discussion. In a recent report Mackenzie (3) postulates that the action of the sulfonamides differs from that of the thioureas and that this difference is illustrated when sodium iodide is given in conjunction with thiouracil or sulfaguanidine. He observed that the response to thiouracil was affected in two ways by the addition of sodium iodide to the diet of the rat. Small amounts of iodide inhibited the thyroid enlargement produced by thiouracil but had

no effect on the hyperplasia. Larger amounts of iodide suppressed the hyperplastic change that usually accompanies the enlargement of the gland. However when sulfaguanidine and sodium iodide were given together "iodide neither reduced the size of the thyroid nor inhibited the degree of hyperplasia. On the contrary a high level of iodide actually potentiated the goiterogenic action of low levels of sulfaguanidine and increased the weight of the gland by 30 to 40 per cent. These observations are of particular interest to us as we administered either Lugol's solution or sodium iodide along with the sulfadiazine to the patients and found that this method of therapy reduced the incidence of severe postoperative reactions and controlled thyroid crises when it

*According to the U.S.P. formula for Lugol's solution, it contains 1.6 per cent iodine, 5 per cent of which is free or elemental iodine and 7.6 per cent of which is present as iodide.

Fig. 1. Microscopic sections from the thyroid glands of Cases 524 and 497 (second operation). Both of the patients received 8 grams of sulfadiazine in the 24 hour period prior to operation. Left, Case 524 had been receiving Lugol's solution for 5 months prior to operation. The basal metabolic rate before operation was +13 per cent. There is pronounced hyperplasia of the gland and also evidence of some involution with colloid deposition. Right, in Case 497 this is the section of the thyroid gland removed at the 2nd stage

of a 2 stage thyroidectomy. The patient received sulfadiazine prior to this operation. He had been receiving Lugol's solution since before the first operation a total period of 210 days. This section shows colloid deposition and also areas of remaining hyperplasia. The microscopic section from the gland removed at the first operation, at which time no sulfadiazine was given, is shown in Figure 2. There does not seem to be any significant difference in the degree of hyperplasia or colloid deposition shown in these sections.

Fig. 2. Microscopic sections from the thyroid glands of Cases 483 and 497 (first stage operation). These patients did not receive sulfadiazine preoperatively. The sections show hyperplasia and areas of involution with colloid deposition. The basal metabolic rate in Case 483, left, prior to operation was +34 per cent, and in Case 497, right, it

was +38 per cent. The course in these 2 patients is shown in Charts 1 and 2. The microscopic section in Case 497 should be compared to the microscopic section from the gland of this same patient shown in Figure 1 as the latter was removed at the second operation prior to which the patient received sulfadiazine.

mit a goiterogenic effect. In this regard the observations of Astwood and associates may be of interest. They reported that in rats histological changes are visible in the thyroid gland 48 hours after the administration of the sulfonamides or the thioureas. The minimal effective dose of sulfadiazine reported for rats was 4.2 milligrams per 100 grams of body weight. With larger doses the effect was visible earlier. The body weight of the hyperthyroid patients in our group did not exceed 70 kilograms and on this basis the dose of sulfadiazine given before operation was about 8.8 milligrams per 100 grams of body weight. The possibility does, therefore, exist that the sulfadiazine might have exerted some goiterogenic effect which the already hyperplastic state of the gland masked. This point deserves further investigation. Another interesting fact was that sulfadiazine was effective in control

ling the rise of temperature and heart rate and the other signs of thyroid crisis if they occurred after complete removal of the gland. This is illustrated in Case 490 in whom thyroid crisis occurred after the second stage of the operation when removal of all remaining thyroid tissue was done. One of the enigmas of thyroid crises has been that it can occur after subtotal thyroidectomy when the amount of thyroid tissue remaining in the patient is small. This is again illustrated in Case 297 (Chart 8) a patient operated on before sulfadiazine was used who developed thyroid crises after the second stage operation and died. Also in a recent report by McArthur Rawson Means, and Cope of 25 patients developing thyroid crises after operation 13 had had subtotal thyroidectomies. The fact that thyroid crises can occur after as well as before removal of the thyroid gland suggests that this reaction may

not originate primarily in the thyroid. The abnormal stimulus which precipitates the storm may well arise elsewhere in the body and may reflect a severe disturbance in hormonal balance. From our experience with these patients sulfadiazine has what might be considered a hitherto undescribed effect on thyroid crises. It does not seem plausible to invoke the anti-infective or goiterogenic actions of the drug to explain this phenomenon. Thus the use of sulfadiazine may constitute another of the empiric procedures to be added to those already used in the management of the patient with hyperthyroidism. One must acknowledge that most of the procedures utilized in the treatment of this disease including thyroidectomy are empiric.

SUMMARY

Eighty-five thyroidectomies were done on 75 patients with thyroid disease. 54 of the patients had severe hyperthyroidism. In addition to the usual preoperative therapy with Lugol's solution most of the patients received 8 grams of sulfadiazine in the 24 hours before operation. The postoperative course in these patients was not attended by any severe reaction and the temperature and pulse rate were well controlled. In patients not receiving the sulfonamide before operation the drug was given after operation when the signs suggestive of thyroid crisis occurred, i.e. rapid heart rate, restlessness and a rise in temperature to 101 degrees. In every instance the

temperature and heart rate decreased and the patient's condition improved. This also occurred when sulfadiazine was given to patients showing signs of thyroid crises before operation. The effect of the sulfadiazine occurred within 12 hours of its administration. In this group of patients treated with sulfadiazine and Lugol's solution there were no deaths whereas in a similar group of 75 patients receiving Lugol's solution and operated upon there were 4 deaths.

Sulfadiazine undoubtedly helped control any infection that might have been responsible for the rise in temperature. In addition as the drug is known to exert a goiterogenic effect this may also have contributed to its effectiveness. In view however of the rapidity with which the drug controlled the signs of thyroid crises the suggestion is made that sulfadiazine may have had an effect on the extrathyroid mechanism initiating the reaction known as thyroid crisis.

ACUTE PNEUMOCHOLECYSTITIS

CARL J. HEIFETZ, M.D. and H. R. SENTURIA, M.D., St. Louis, Missouri

BY acute pneumocholecystitis is meant an acute infection of the gall bladder characterized by the production of gas within the gall bladder lumen. The diagnosis can be made radiographically the gall bladder being visualized through the contrast medium of gas. The term acute pneumocholecystitis seems preferable to 'pyopneumocholecystitis' as advocated by Simon since there is no certainty that all cases have pus in association with gas. The name emphysematous cholecystitis proposed by Schmidt and Stevenson (17-18) also lacks inclusiveness since the emphysematous pericholecystic infiltration of gas is not invariably present.

The recognition of gas infection of the gall bladder as an entity is almost solely a product of the roentgenological literature. This is understandable because of the almost pathognomonic rôle of roentgenographs. The surgeon should be no less interested for certain peculiar features of this disease pose problems in its surgical management. That gas-forming organisms are frequent inhabitants of the biliary tract has been known for years. These organisms are not unlike those present in the intestinal tract. While a majority of normal and diseased gall bladders are sterile, others contain a wide variety of bacterial flora, headed in frequency by the *Escherichia coli communis* and the *Clostridium perfringens* (1-8). Besides the *Clostridium perfringens*, other gas-forming organisms often difficult to classify, may exist in the bile tract. For the most part they seem to exist as harmless saprophytic inhabitants. Occasionally they manifest themselves by the postmortem production of gas in the bile radiates (21). Demonstration of gas in the gall bladder is perhaps most frequent in fistulas between the gastrointestinal tract and the gall bladder—a condition which bears little clinical relationship to the subject of this paper.

Examination of the literature of the last 45 years has uncovered only 8 bona fide cases.

From the Departments of Surgery and Radiology of the Jewish Hospital of St. Louis.

Aided by the Louis M. Monbether Memorial Fund.

of acute pneumocholecystitis. Kirchmayer was evidently the first to draw attention to the condition. In 1925 he described a case of severe acute cholecystitis in a 64 year old male patient who at operation presented a gangrenous gall bladder distended with gas and pus, some of the gas having escaped into the peritoneal cavity through a perforation. Gram positive gas producing anaerobic bacilli without spores were recovered from the gall bladder contents and wall. The gall bladder was removed and recovery was uneventful. No roentgenologic studies were made.

Hegner in 1931 was the first to recognize this disease preoperatively. His patient was a 62 year old man who had symptoms and signs of severe acute cholecystitis. A scout film of the gall bladder area showed a pear-shaped gas shadow corresponding in shape and size to an enlarged gall bladder. During several days observation the amount of the gas increased and small infiltrations of gas bubbles could be demonstrated in the pericholecystic area. At operation emphysema of the gall bladder wall and gas under pressure within the acutely inflamed gall bladder were found. The gall bladder was drained. Death occurred of pulmonary embolism on the fourth postoperative day. No calculi were demonstrated at operation but a large mulberry stone was found in the gall bladder at autopsy. Atypical *Bacillus welchii* were recovered from the gall bladder pus obtained at operation and autopsy.

A year later Simon described a similar case in a 32 year old man. An admission diagnosis of acute cholecystitis was made. On roentgenographic examination gas over a fluid level was demonstrated within the gall bladder. In addition there were small infiltrations of gas in the pericholecystic area. The gastrointestinal series showed no communication between the intestine and the gall bladder although the imprint of the enlarged gall bladder in the adjacent small intestine could be shown. While the general condition of the patient improved, the roentgenogram showed more pericholecys-

tic infiltration so that surgery was performed. When the peritoneum was opened gas and bile stained pus escaped from a pocket at the fundus of the gall bladder. The gall bladder was gangrenous and there were a number of small perforations. Many calculi were present. Cholecystectomy was performed. Direct smears of the pus showed spores and anaerobic type organisms. No culture was made. The patient recovered. Simon thought that the infection might be blood borne.

Schmidt in 1938 added a case of a 38 year old man with symptoms of acute cholecystitis whose roentgenogram showed gas filling the gall bladder but no pericholecystic involvement. Gastrointestinal series ruled out a communication with the intestine or stomach. Spontaneous recovery occurred. The roentgenograms were so similar to those described by Hegner and Simon that Schmidt did not hesitate to consider this a case of gas infection of the gall bladder despite lack of operative or autopsy proof. Some hint as to the mechanism of recovery could be obtained from the cholecystograms taken during partial recovery when the cystic duct was sufficiently patent to permit entrance and some concentration of the dye.

In 1940 del Campo and Otoro described 2 cases in which the bile tract could be visualized radiographically. In the first case there was a fistulous communication with the gastrointestinal tract and it cannot be included in this series. The second case was a 74 year old man who presented symptoms of acute cholecystitis. The initial roentgenograms showed no gas in the bile tract but roentgenograms on the 5th hospital day showed that the medium and large bile ducts were filled with gas although no gas was seen in the gall bladder. When operation was performed the following day a large amount of gas under pressure together with reddish yellow pus was aspirated from the gall bladder. The acutely inflamed organ was drained. *Clostridium perfringens* was recovered from the pus. Death occurred on the fourth postoperative day. The postmortem examination revealed numerous large calculi in the gall bladder and common bile duct one impacted in the ampulla of Vater. Necrotic areas containing gas were

found in the lungs myocardium kidneys and liver but these were not cultured. This case differs considerably from the others its inclusion in this series may be open to question.

Stevenson (17 18) in 1944 described 3 cases in men aged 52 63 and 64. All had symptoms and signs of acute cholecystitis. The accidental finding of gas in the gall bladder and pericholecystic tissues led to the diagnosis of emphysematous cholecystitis. Two patients were subjected to surgery and the acutely inflamed and gangrenous gall bladders contained gas pus and calculi. The peritoneal exudate of 1 case was cultured and revealed 'aerobic and anaerobic streptococci'. The third patient presented a similar picture and made a recovery without surgery despite the fact that gas had infiltrated into the pericholecystic tissues. This patient received intensive antiseptic infection therapy including polyvalent antiserum sulfathiazole and roentgen therapy and Stevenson is of the opinion that the treatment may have helped the patient recover without surgery.

The foregoing cases are the only ones falling into this clinical and roentgenologic classification. Other reports demonstrating gas-forming organisms in the gall bladder are not uncommon (5 10 13 19) but they are cases in which *Clostridium perfringens* (Frankel's or Welch's bacillus) was found in routine cultures from pus recovered at operation or autopsy. Mention of gas in the gall bladders was not made except in the case of Hallé and Marquéz in which on postmortem examination gas was present in the gall bladder and liver very likely a postmortem change.

CASE REPORTS

CASE 1: H. W. white male, aged 52 years, was admitted to the Jewish Hospital of St. Louis on October 3, 1946, 2 days after the onset of epigastric and right upper quadrant pain radiating to the back and midthorax, and followed by a bloated feeling and nausea. Two hours after the onset he was seen by a physician who administered morphine. This treatment was effective during his only previous similar attack of pain 4 months earlier following which an electrocardiogram showed a normal cardiac mechanism. He slept for 8 hours and awakened with a continuation of right upper quadrant pain the radiation to the back and thorax having subsided. Several loose bowel movements were noted after the onset subsequently the bowels were constive. When

Fig. 1. Case 1. Flat plate of gall bladder area showing pear shaped gas-containing gall bladder. The gall bladder is sharply outlined and there is no gas in the pericholecystic tissues.

Fig. 2. Case 1. Eight days later the gall bladder shows increase in size and now assumes more globular outline. The margins of the gall bladder are irregular due to gas infiltrating into the pericholecystic tissues.

his physician felt a tender mass in the right upper quadrant the patient was admitted with a clinical diagnosis of acute cholecystitis.

Physical examination. The patient was a middle aged man apprehensive, perspiring freely, and complaining of constant abdominal pain. The clinical appearance belied the low temperature (100.6 rectal) and slow pulse rate (84 per minute). The sclerae were faintly icteric. The upper abdomen remained splinted on deep breathing. Intestinal peristalsis was audible. A smooth, very tender globular mass 3 inches in diameter extended below the right costal margin and merged with respiration. On either side of the mass the liver edge could be felt one to two fingerbreadths below the costal margin. Palpation was easiest accomplished by light pressure, deeper pressure causing enough muscle guard to obscure the mass. R bound tenderness was minimal.

Laboratory data. Urinalysis was negative except for two-plus urobilinogen. White blood cells numbered 13,800, red blood cells 4,080,000, hemoglobin 12.8 grams. Differential count showed basophil 0, eosinophils 2, myelocytes 0, juvenile form 0, stab form 16, segmented form 67, lymphocytes 14, monocytes 1. Diastase 35, nonprotein nitrogen 19, blood sugar 107, Kahn negative, cholesterol 303, icterus index 10, total protein 5.8, albumin 3.0, globulin 2.8.

Course. Admission roentgenograms showed the gall bladder distended with gas, the wall sharply outlined (Fig. 1). Because the optimum period for performing cholecystectomy in the acute stage had already passed and because the clinical findings showed some improvement it was decided to postpone operation. The experiences of Schmidt and Stevenson in similar cases, which recovered without operation, somewhat influenced this decision. The patient received 20,000 units of polyvalent gas gangrene antitoxin intramuscularly initially and 10,000 units thereafter every 12 hours. In addition, 50,000 units of penicillin every 3 hours intramuscularly and 1 gram of sulfadiazine every 4 hours were administered. A diet high in carbohydrates and proteins was well tolerated. The temperature and pulse rate remained relatively low and the acute inflammatory signs in the upper abdomen showed some alleviation. But the gall bladder slowly increased in size, and the leucocyte count remained elevated. A roentgenogram made on October 10 showed an increased amount of trapped gas in a more globular gall bladder whose margins were irregular due to gas infiltrating into the pericholecystic tissues (Fig. 2). On October 8 the sulfadiazine and on October 9 the penicillin were discontinued without appreciably altering the clinical course. On October 13 the roentgenogram showed an irregular pattern of gas over

Fig 3. Case 1. Three days later there is an irregular pattern of gaseous infiltration in the gall-bladder bed with widespread pericholecystic infiltration.

Fig 4. Case 1. One day before operation there is an increase in the area of involvement and the size of the gall bladder with less sharp definition of its outline.

infiltration in the gall bladder bed and a more widespread pericholecystic infiltration (Fig 3). In the meanwhile the temperature and pulse rate became normal, although the gall bladder was still enlarged and tender and the leucocyte count remained elevated. For the next few days the condition remained unchanged. Beginning October 19 daily rises in temperature to 100 degrees were noted. On October 21 the roentgenograms showed an increase of gas, both within the gall bladder and in the surrounding tissues (Fig 4).

The following day, October 22 surgery was performed under general anesthesia. A short muscle splitting upper right rectus incision was made directly over the palpable mass. When the peritoneum was opened gas under pressure hissed out of a walled off abscess cavity which included the necrotic fundus of the gall bladder. Then a mixture of bile stained pus and numerous small black, bilirubinate calculi were removed by suction from what was apparently the gall-bladder lumen. Complete examination of the gall bladder was not possible but no large calculus could be demonstrated in the region of the cystic duct. A drainage tube was inserted. No closure was made.

Fresh pus obtained from the gall bladder was sent to the laboratory for culture. Aerobic cultures were made in tryptose-phosphate broth on blood agar

plates and in Endo's medium. Anaerobic cultures were made on blood agar plates and in thioglycollate medium. Particular search was made for *Clostridium perfringens* litmus milk being used but its presence could not be detected. *Streptococcus fecalis* an aerobic and facultatively anaerobic organism which does not produce gas was isolated and identified after growth in milk in 2 per cent and in 6 per cent saline media. An aerobic and facultatively anaerobic member of the paracolon group related to *Escherichia coli* was isolated and identified by cultivation on Kligler's medium the usual sugars milk the tests for indol production the reduction of nitrates to nitrites, Voges-Proskauer reactions and the utilization of citrate. Gram negative nonspore producing anaerobic rods belonging to the *Bacteroides* group which produced no gas in sugar milk or blood serum media were found after repeated thioglycollate cultures. None of the three types of bacteria found was by itself a gas producer. Whether a combination of these organisms could produce gas commensally is not known.

After operation the drainage was first purulent later serous. Occasionally small calculi of the same type as those seen at operation were extruded. No bile drainage occurred at any time. The drainage tube was removed on the eleventh postoperative day and the patient was discharged from the hospital on

Fig. 5. Case 1. The gall bladder is elongated and distended and contains many medium sized nonopaque stones which are visualized by contrast with the gas in the lumen of the gall bladder (arrows). The wall of the gall bladder is visualized by a thin zone of pericholecystic gas.

Fig. 6. Case 2. In this roentgenogram the gall bladder is smaller, the pericholecystic gas infiltration is more marked especially near the neck of the gall bladder (arrows). The calculi and gall bladder wall are less distinct.

the thirteenth postoperative day. The wound healed rapidly to an opening 1 centimeter in diameter and remained in this condition for a number of days. On December 6 a piece of necrotic tissue was seen protruding through this opening. When traction was made on this tissue the necrotic cast of the gall bladder wall was easily and painlessly extracted. The lumen still contained several small calculi. In another week the wound was completely healed and the subsequent course has been uneventful.

CASE 2. M. B., white female aged 57 years, a patient of Dr. C. H. Kilker, was admitted to the Missouri Baptist Hospital on February 20, 1947, with an admission diagnosis of acute cholecystitis. For several years she had had recurrent attacks of epigastric distress, nausea and vomiting, aversion to fatty and fried foods. There was also a tendency to constipation and a recent weight loss over several weeks of 20 pounds. During the previous 3 weeks the attacks had been located more in the right upper quadrant than in the epigastrium and had become increasingly severe and frequent. The attack for which she was admitted was of 2 days duration. It was the most severe one and was accompanied by vomiting.

Physical examination disclosed a middle aged woman in considerable distress from abdominal pain.

The rectal temperature was 101 degrees and the pulse rate 90 per minute. There was marked tenderness, rigidity and rebound pain in the right upper quadrant and epigastrium. A smooth tender mass moving with respiration suggestive of the gall bladder could be made out.

Urinalysis was negative. White blood cells numbered 15,600. Differential count revealed basophils 0, eosinophils 0, myelocytes 0, juvenile forms 0, stab form 20, segmented form 57, lymphocytes 14, mononuclears 0. Kahn reaction negative.

A roentgenogram taken February 21, the day after admission, showed an elongated gall bladder distended with gas. The wall was easily identified by a thin zone of pericholecystic gas and in the fundus multiple shadows suggestive of calculi were present (Fig. 5). The patient received 30,000 units of penicillin intramuscularly every 3 hours. No sulfonamides or gas gangrene antitoxin were administered. A high carbohydrate diet was well tolerated. Considerable improvement in the general condition was noted and the local tenderness and rigidity decreased although the gall bladder remained enlarged and tender. On February 22 the roentgenogram showed essentially the same findings. X-ray examinations were repeated on February 27 following the administration of dye. No dye entered the gall bladder.

der but the organ was again visible by virtue of its distention with gas. The calculi and gall bladder wall were less distinct and some escape of gas into the pericholecystic area could be made out (Fig. 6). The penicillin was discontinued on February 26. Because of the persistently enlarged and tender gall bladder it was decided to perform surgery. On March 3 under cyclopropane and curare anesthesia the abdomen was entered through and upper right rectus muscle-splitting incision. The gall bladder was obscured by an adherent mass of omental and intestinal adhesions, many of which allowed the escape of gas probably trapped outside the gall bladder wall. The gall bladder was tense, acutely inflamed and its wall presented small gangrenous patches through which the gas had apparently escaped but no gross perforation was visible. It removed after considerable difficulty and there was spillage of purulent medium-sized faceted calculi together with escape of gas from the lumen. During removal a calculus was dislodged from the region of the cystic duct (this was collected for bacteriologic studies). Sulfathiazole crystals were sprinkled into the area and the abdomen was closed in layers without drainage.

Identification of the organism proved most difficult. Numerous cultures and subcultures were made in a wide array of media and after several months study the organism was identified as *Clostridium histolyticum*. This clostridium is occasionally present in human stool but information as to whether it has been recovered from the human gall bladder is not at hand. It is an obligate anaerobe closely related to *Clostridium perfringens* which produces terminally or subterminally round spores, which do not cause swelling of the organism. It hemolytic properties vary. It produces acid and gas from dextrose and lactose although saccharolytic powers are limited. Since no other organism was detected it is assumed that *Clostridium* form was the gas-forming organism in this case.

After operation penicillin was again given for a week. Sodium sulfadiazine 6 gram daily was administered intravenously from March 5 to March 10. There was profuse purulent drainage for several days but this diminished gradually. On March 13 the drain was removed. By March 25 the wound had completely healed and the patient was discharged.

Chart 1 is a graphic representation of the clinical course of the two cases.

DISCUSSION

An appraisal of the cases of acute pneumocholecystitis brings forth a number of interesting facts (Table I). All the patients but one were male—a circumstance which none of the associated data seems to explain. In most of the cases the condition occurred in the sixth and seventh decades of life but in 2 it occurred in the fourth decade. One would suppose in consideration of the usual picture of gas bacil-

lus infections elsewhere that acute pneumocholecystitis is a fulminating and invariably fatal disease. This was not true except in the case of Del Campo and Otero. The composite picture is one of persistent acute upper abdominal pain usually after previous attacks of pain associated with the gall bladder. The temperature is elevated but not to a high degree. Tenderness and rigidity are prominent features and when the rigidity permits, the gall bladder and occasionally the liver edge can be felt. When icterus is present, it is not marked. This picture of acute inflammation of the gall bladder is not unlike that of other cases of acute cholecystitis or empyema of the gall bladder. In fact there is little to indicate how cases of acute pneumocholecystitis can be distinguished without roentgenology from the general run of acute gall bladder infection without the presence of gas in the gall bladder. There is however a tendency for the inflammatory signs to persist and failure of the attack to resolve would lead one to consider the development of gangrene and perforation complications which certainly do not depend upon the existence of a gas infection. It is evident therefore that the presence of gas in an acutely inflamed gall bladder is an incidental finding although as will be shown, its presence makes for additional problems.

In evaluating the significance of the rôle of gas in acute pneumocholecystitis certain considerations of etiological importance in ordinary cases of acute cholecystitis should be discussed. There is now rather universal agreement that a prime etiologic factor is obstruction at the outlet of the gall bladder (4, 22). Berk reported that blockage of the outlet of the gall bladder by calculi was found in over 92 per cent of the cases of acute cholecystitis collected from the literature. Other causes of obstruction have been noted for example angulations and kinks at the junction of the cystic duct and gall bladder, anomalous cystic blood vessels, adhesions and fibrosis, periduodenitis, enlarged lymph nodes, etc.¹ That obstruction alone generally does

¹ To explain these rare cases of acute cholecystitis in which no obstruction is found, some have postulated the reflex of pancreatic enzymes which upon becoming activated by bile produce inflammatory changes of the gall bladder (5). A possible mechanism for this reflex has been demonstrated experimentally (6).

Case 1

Chart 1

Case 2.

not lead to acute cholecystitis seems well established. Womack and Bricker found no evidence of cholecystitis after occlusion of the cystic duct in dogs if the bile imprisoned within the gall bladder was replaced by saline. They demonstrated that the components of bile itself were partly responsible for the production of acute cholecystitis. The evidence is overwhelmingly against the primary rôle of bacteria in acute cholecystitis. Bacteriologic studies of normal and diseased gall bladders by Andrews and Henry, Eliason and Stevens, and others conclude that at least 50 per cent of gall bladders of all types normal chronic acutely inflamed acutely inflamed with or without calculi contain no culturable bacterial flora. The remainder of the cases contained a

bacterial flora of varying richness and variety a flora which frequently bears a close resemblance to that of the intestine indicating perhaps reflux communication between the intestine and the biliary tract.¹ The cases of acute pneumocholecystitis presented here show a similar lack of uniform bacterial flora (Bacteriological studies in these cases were supervised by Dr. Moyer Fleisher). While the bacteriological studies leave much to be desired sufficient studies have been done to indicate that these cases have been associated with a variety of organisms aerobic anaerobic facultatively aerobic, atypical *Bacillus welchii* anaerobic spores, etc. In the cases in which

It must be concluded that the *Clostridium falliforme* recovered from Case 2 originated in the intestine.

der but the organ was again visible by virtue of its distention with gas. The calculi and gall bladder wall were less distinct and some escape of gas into the pericholecystic area could be made out (Fig. 6). The penicillin was discontinued on February 26. ¹ To explain those rare cases of acute cholecystitis in which obstruction is found, some have postulated the release of pancreatic enzymes, each upon becoming activated by bile producing inflammatory changes of the gall bladder (4). A possible mechanism for this release has been demonstrated experimentally (16).

gas-producing infections. Accordingly the demonstration of gas in an acutely inflamed gall bladder should strongly favor a decision for early surgery even emergency surgery. The procedure of choice would seem to be cholecystectomy particularly in the first stages of inflammation. Experience with several of these cases has demonstrated that spillage of pus locally in the peritoneal cavity has been well tolerated. Cholecystostomy may be and has been judiciously used when conditions preclude removal of the gall bladder. Accidental spillage of gall bladder contents during operation should not be unduly feared.

Those who have had the opportunity to treat cases of acute pneumocholecystitis have done so with considerable apprehension. The facts do not indicate that this anxiety is justified to a much greater degree than in other cases of acute cholecystitis. True no group of cases bearing a mortality rate of 20 per cent can be dismissed lightly. The causes for the fatalities however are interesting. One death was proved to be due to pulmonary embolism, a complication not necessarily associated with the gas infection. The other death was the only case from which *Clostridium perfringens* was recovered. This patient showed involvement of other parts of the biliary system and remote organs facts which cast some doubt on the validity of including it in this series. The favorable outcome of the other cases contradicts the conclusion of Walters and Snell that gas infection of the gall bladder usually terminates fatally.

Pneumocholecystitis can be differentiated from the usual variety of acute cholecystitis only by the roentgenogram. While the cholecystogram is not indicated in acute cases the scout film of the gall bladder area will aid in identifying this unusual type of infection. More general use of the plain film in clinical cholecystic disease may uncover many more cases of pneumocholecystitis than have been recognized previously and prepare the surgeon for a more intelligent approach to the distinctive problems which this condition presents.

SUMMARY

Eight cases of acute pneumocholecystitis have been collected from the literature and

reviewed. Two additional cases diagnosed preoperatively are added to the literature.

By pneumocholecystitis is meant acute infection of the gall bladder characterized by the production of gas within the gall bladder. Pericholecystic infiltration with gas may or may not be present.

Necrosis of the gall bladder with perforation is a frequent finding. However the virulence of the infection is relatively less than in gas bacillus infections elsewhere in the body.

Bacteriologically, no constant distinctive organisms are demonstrable.

Surgical therapy alone is effective since the gall bladder wall is subject to greater tension when gas is present and there is a consequent greater risk of gangrene and perforation.

Polyvalent gas antiserum, sulfonamides, penicillin and roentgen therapy are of questionable value in the management of acute pneumocholecystitis.

Routine scout films of the gall bladder area in clinical cholecystic disease will aid in the recognition of this distinctive form of acute cholecystitis.

studies have been directed to the presence of gas-forming organisms. *Clostridium perfringens* has been looked for but seldom seen in spite of the fact that recognition of the organism poses no inordinate problems. It is likely then that the infections of the gall bladder which produce gas are rarely associated with *Clostridium perfringens* but instead with other gas-forming organisms. Another inference is that the development of acute cholecystitis in these cases occurs independent of the bacteria present and the formation of gas is a rare complication which depends upon the presence of a gas-former within the gall bladder at the time and more important upon conditions enhancing their gas-producing potentialities. That these poorly understood conditions are important can be adduced from the fact that many acute gall bladders contain *Clostridium perfringens* and other gas-forming organisms without producing gas.

It might be argued that the cases of Schmidt and one of Stevenson's cases (17) lacking surgical confirmation should not be included in this group of cases. This poses the question does the finding of gas in the gall bladder indicate an acute pneumocholecystitis? Not usually. Perhaps an even more common cause of gas in the gall bladder is a fistula between this organ and the gastrointestinal tract. It should also be noted that gas may accumulate in the gall bladder as well as in other organs in cases of generalized perfringens infection and as a postmortem change. If these possible sources are ruled out the finding of gas in the gall bladder accompanied by clinical evidence of acute cholecystitis must be considered indicative of acute pneumocholecystitis.

The preoperative recognition of acute pneumocholecystitis presents certain problems in its management. The administration of polyvalent antiserum perhaps first comes to mind, and was employed in 2 cases of this series. Its effectiveness is open to question as might well be expected where the gas-forming organism seems to play a secondary rôle. It is true that the patient to whom Stevenson gave it recovered without surgery, but so did Schmidt's patient who received no antiserum. The profuse use of antiserum in Case 1 of this report

seems to have little altered the course of the disease. The antisera available would probably not be effective against most of the infections because of lack of specificity. Moreover the effectiveness of antisera for gas infection in general has been subject to dispute. (6) The sulfonamides and penicillin likewise were employed in some of these cases, and while their effectiveness cannot be disproved the course of the cases in which they were employed did not differ significantly from those in which they were not. Here, too, these therapeutic agents have not been especially effective in gas gangrene. (14) Roentgen therapy used only by Stevenson, has yet to prove its effectiveness for acute pneumocholecystitis as well as for ordinary gas gangrene.

This brings us to the discussion of the surgical therapy which alone seems effective. Since acute pneumocholecystitis behaves for its most part as do other types of acute cholecystitis the first impulse would be to treat the two conditions alike. Unfortunately there is considerable disagreement as to the correct management of acutely infected gall bladders; some prefer emergency cholecystectomy in the hope of avoiding the complications of gangrene and perforation and of decreasing the mortality and mortality rates while others choose a more conservative course delaying surgery until complications are imminent or until a quiescent period occurs. It is not within the scope of this discussion to present the arguments on either side of this controversy but it should be mentioned that we employ either early or delayed surgery in our cases, attempting to follow a course which seems best suited for the particular case at hand. Cases of acute pneumocholecystitis could presumably be handled similarly were it not for the fact that the mechanics of gas production considerably alter the situation. While the element of infection is not significantly different there can be little doubt that the gall bladder walls are subject to greater tension when gas is present and consequently to an increased risk of gangrene and perforation. The tendency for the wall to become necrotic and for gas to escape into the pericholecystic tissues so frequently demonstrated in this series, indicates a much greater incidence of complications than in non-

gas-producing infection. Accordingly the demonstration of gas in an acutely inflamed gall bladder should strongly favor a decision for early surgery even emergency surgery. The procedure of choice would seem to be cholecystectomy particularly in the first stages of inflammation. Experience with several of these cases has demonstrated that spillage of pus locally in the peritoneal cavity has been well tolerated. Cholecystostomy may be and has been judiciously used when condition preclude removal of the gall bladder. Accidental spillage of gall bladder content during operation should not be unduly feared.

Those who have had the opportunity to treat cases of acute pneumocholecystitis have done so with considerable apprehension. The facts do not indicate that this anxiety is justified to a much greater degree than in other cases of acute cholecystitis. True no group of cases bearing a mortality rate of 20 per cent can be dismissed lightly. The causes for the fatalities however are interesting. One death was proved to be due to pulmonary embolism a complication not necessarily associated with the gas infection. The other death was the only case from which *Clostridium perfringens* was recovered. The patient showed involvement of other parts of the biliary system and remote organs facts which cast some doubt on the validity of including it in this series. The favorable outcome of the other cases contradicts the conclusion of Walters and Snell that gas infection of the gall bladder usually terminates fatally.

Pneumocholecystitis can be differentiated from the usual variety of acute cholecystitis only by the roentgenogram. While the cholecystogram is not indicated in acute cases the scout film of the gall bladder area will aid in identifying this unusual type of infection. More general use of the plain film in clinical cholecystic disease may uncover many more cases of pneumocholecystitis than have been recognized previously and prepare the surgeon for a more intelligent approach to the diagnostic problems which this condition presents.

SUMMARY

Eight cases of acute pneumocholecystitis have been selected from the literature and

reviewed. Two additional cases diagnosed preoperatively are added to the literature.

By pneumocholecystitis is meant acute infection of the gall bladder characterized by the production of gas within the gall bladder. Pericholecystic infiltration with gas may or may not be present.

Necrosis of the gall bladder with perforation is a frequent finding. However the virulence of the infection is relatively less than in gas bacillus infections elsewhere in the body.

Bacteriologically no constant distinctive organisms are demonstrable.

Surgical therapy alone is effective since the gall bladder wall is subject to greater tension when gas is present and there is a consequent greater risk of gangrene and perforation.

Polyvalent gas antiserum sulfonamides penicillin and roentgen therapy are of questionable value in the management of acute pneumocholecystitis.

Routine scout films of the gall bladder area in clinical cholecystic disease will aid in the recognition of this distinctive form of acute cholecystitis.

ANESTHESIA

The anesthetic of choice is one that will produce the best relaxation of the muscles of the anal canal and perineum. My choice is spinal anesthesia produced by 5 to 6 milligrams of pontocaine hydrochloride (dimethyl aminoethyl p-n butylaminobenzoate hydrochloride) in 1 to 2 cubic centimeters of spinal fluid or 25 to 50 milligrams of procaine hydrochloride crystals dissolved in 1 cubic centimeter of spinal fluid which are injected between the third and fourth lumbar vertebrae. Saddle block anesthesia confined to the perianal and perineal areas may be effected by keeping the patient in the sitting position for about 30 seconds after the completion of the intraspinal injection. The incidence of post spinal headaches has been reduced by employing small puncture needles (22 to 25 gauge)

by keeping the patient in a horizontal position for from 8 to 24 hours after operation and by hydration. If headaches do occur they can be relieved by hydration through parental and enteral routes with 2,000 to 3,000 cubic centimeters of 5 per cent dextrose solution with or without saline. The administration of the sodium salt of niacin also has been suggested but its efficacy remains to be proved. This vitamin is given intravenously in doses of 100 milligrams (about 2 grains) and repeated if necessary. This substance also may be administered orally in doses of 200 to 400 milligrams (4 to 8 grains) 3 to 4 times daily with hydration.

Caudal and transsacral block anesthesia also may be employed. This is an effective but a difficult and time-consuming procedure even in the hands of an expert anesthetist. Be-

THE SURGICAL TREATMENT OF CHRONIC ANAL FISSURE

ROBERT TURELL, M.D. New York New York

CHRONIC anal ulcers (fissures)¹ are usually found in the posterior arc of the anal canal although they may occur in other parts of the anal outlet. This lesion is invariably associated with adjacent and subjacent induration and inflammation infection or inflammation of the preformed anal ducts anal glands, and anal crypts. Spasm (dysfunction) and fibrosis of the subcutaneous component of the external anal sphincter muscle also are frequently encountered. A sentinel pile and fibroepithelial polyps (hypertrophied papillae) frequently accompany chronic anal ulcers (Figs. 1 and 2). In agreement with Morgan I ascribe the prevalence of anal ulcers in the posterior aspect of the anal canal to the preponderance of anal crypts and the consequent greater likelihood of infection in this anatomic area (5).

An attempt has also been made to explain the pathogenesis of anal ulcer on the basis of the peculiar anatomic arrangement of the various components of the external anal sphincter muscle (1) and to the anatomic relationship of the posterior anal wall to the posterior rectal wall (2). The superficial component of the external anal sphincter muscle has a Y-shaped origin and insertion; it lies above and external to the subcutaneous component which is an unsupported circular muscle surrounding the anal canal. Thus the subcutaneous portion of the external anal sphincter muscle lies like a bar across the crook of a Y and is according to Blaisdell (1) subject to frequent defecatory trauma; this subcutaneous sphincteric component has no influence upon anal incontinence. Blaisdell pointed out that because the junction of the posterior walls of the rectum and anus forms a right angle the sphincteric muscle is vulnerable to trauma which is produced by the weight of the fecal mass.

The treatment of chronic anal ulcer is always surgical. In this paper a rational operative procedure based on the experience obtained in civilian and military practice in the treatment of 270 patients, is described and illustrated. The operation comprises wide excision of the ulcer bearing area the extirpation of the involved anal crypt or crypts with the sentinel pile and polyps, and the performance of a posterior sphincterotomy (Figs. 3, 4, 5 and 6). The accompanying drawings are based on sketches made by the artist in the operating room.

PREOPERATIVE MANAGEMENT

The patient is admitted to the hospital one 12 hours prior to operation. The perineal and perianal regions are shaved and washed with soap and water. The dorsolumbar portion of the back is also shaved washed with soap and water painted with a tincture containing 3 per cent of iodine and covered with a sterile towel which is held in place by means of adhesive plaster. The intestinal preparation consists of a saline enema given 6 to 8 hours before operation.

Suitable sedation consists of the oral administration of a drug of the barbiturate group. Usually a long acting barbiturate, such as phenobarbital in a dose of 0.090 gram (1½ grains) is given orally about 8 to 12 hours before operation and a short acting barbiturate such as pentobarbital sodium (nembutal) or sodium propylmethylcarbonyl allyl barbiturate (seconal) is administered in doses of 0.090 gram (1½ grains) 1 to 2 hours before the scheduled time of the operation. Morphine sulfate 0.011 to 0.016 gram (¼ to ¼ grain) or demerol hydrochloride 0.100 gram (1½ grains) with atropine sulfate 0.00032 gram (1/150 grain) or scopolamine hydrobromide 0.00032 gram (1/200 grain) is administered subcutaneously 60 to 90 minutes before the patient leaves for the operating pavilion.

¹Regarding the use anal ulcers and "anal fissures, these terms are used interchangeably in this article.

ANESTHESIA

The anesthetic of choice is one that will produce the best relaxation of the muscles of the anal canal and perineum. My choice is spinal anesthesia produced by 5 to 6 milligrams of pontocaine hydrochloride (dimethyl aminoethyl p-n butylaminobenzoate hydrochloride) in 1 to 2 cubic centimeters of spinal fluid or 25 to 50 milligrams of procaine hydrochloride crystals dissolved in 1 cubic centimeter of spinal fluid which are injected between the third and fourth lumbar vertebrae. Saddle block anesthesia confined to the perianal and perineal areas may be effected by keeping the patient in the sitting position for about 30 seconds after the completion of the intraspinal injection. The incidence of post spinal headaches has been reduced by employing small puncture needles (22 to 25 gauge)

by keeping the patient in a horizontal position for from 8 to 24 hours after operation and by hydration. If headaches do occur they can be relieved by hydration through parental and enteral routes with 2,000 to 3,000 cubic centimeters of 5 per cent dextrose solution with or without saline. The administration of the sodium salt of niacin also has been suggested but its efficacy remains to be proved. This vitamin is given intravenously in doses of 100 milligrams (about 2 grains) and repeated if necessary. This substance also may be administered orally in doses of 200 to 400 milligrams (4 to 8 grains) 3 to 4 times daily with hydration.

Caudal and transsacral block anesthesia also may be employed. This is an effective but a difficult and time-consuming procedure even in the hands of an expert anesthetist. Be-

cause of the simplicity of execution and the promptness of anesthesia. I prefer spinal to caudal transsacral anesthesia. Inhalation anesthesia usually cyclopropane is employed only when the patient is apprehensive or refuses other types of anesthesia.

With the employment of the technique to be described it has been unnecessary to utilize the long acting anesthetic solutions for the avoidance of postoperative pain. The use of these drugs also has been avoided because they do not afford an anesthetic effect in many instances and because they may produce an aseptic inflammatory reaction of the tissues into which they are injected eventuating in suppuration and necrosis. In many cases there occurs a delay in the healing process of the wound and an increase in scarring.

TECHNIQUE

After induction of anesthesia, the patient is placed in the proper position on the abdomen and the operating table is adjusted so that a modified jackknife inverted position is obtained.

It is my unflinching practice to perform an anoproctosigmoidoscopic examination prior to the admission of the patient to the hospital except in the presence of very painful lesions such as the condition under discussion. In instances such as this the complete proctologic survey is carried out after anesthesia has been induced.

With the patient in the inverted position the operative field is cleansed with alcohol and painted with tincture of alkyldimethyl benzylammonium chlorides (sephuran chloride).

With a retracting operative anoscope in the anal canal a gauze sponge to which a long piece of silk suture material is tied is placed in the rectum well above the proposed operative site and is anchored to the outside by means of a forceps and a pyramidal incision in the perianal skin is made (Fig. 1). Its summit usually extends about 2 centimeters from the anal verge and ends about 1 centimeter above the pectinate line (mucocutaneous junction). Laterally the incision is made about 0.5 centimeter away from the ulcer bearing area and the sentinel pile (Fig. 3).

The ulcer bearing region and the subcutaneous tissues are dissected free. The subcutaneous component of the external anal sphincter muscle is exposed and visualized (to be dealt with subsequently) and the dissection is continued and the integument of the anal canal and the rectal mucosa is freed for a distance of about 1 centimeter above the pectinate line (Fig. 3). This rather wide dissection is done in order to facilitate the excision not only of the ulcer bearing tissues, but also the sources and channels of infection. A Smith crushing clamp is then applied to the mesal pedicle radially in the long axis of the anus and the diseased tissues are excised. The mucosal pedicle may be dealt with in one of several ways two of which are herewith described: (1) interrupted number zero chromic catgut sutures (the exact number varies with the size of the pedicle) are introduced under the clamp and are tied after the clamp is removed and the crushed portion of the mucosa excised (Figs. 5 and 6). (2) a continuous chromic catgut suture is placed beneath the tip of the clamp and tied. This suture is then looped several times around the shank of the clamp. After the latter is released and removed the loose suture is pulled up and tied. The mucosal stump may be anchored to the submucosal tissues in the level of the pectinate line however this maneuver is usually unnecessary.

The subcutaneous portion of the external anal sphincter muscle which in many instances of chronic anal ulcer is fibrosed and atrophied is now incised in the right angle of its fibers (Fig. 5). If considerable fibrosis exists I excise a small part of this muscle, as shown in Figure 6 in order to prevent early reapposition of this muscle and insure ample drainage which in turn promotes better restitution of the inflamed anorectal tissues. This modified sphincterotomy has been performed in over 100 cases with gratifying results.

Associated pathologic anorectal lesions, such as infected anal crypts or fibroepithelial polyps situated in other parts of the anal canal may be excised. Except for hemorrhoids situated close to the ulcer I prefer not to remove concomitant hemorrhoids as these frequently recede after excision of the ulcer.

Fig 7 (Also see Fig 3) The component parts of the external anal sphincter muscle. The subcutaneous portion is the most superficial. Since it does not influence anal incontinence, the severance of its continuity may be effected safely.

Hemostasis may be secured by gentle pressure with gauze or by clamping the bleeding points with small artery forceps and tying them with double zero plain catgut. In addition the new hemostatic agents such as the gelatin sponge (with or without thrombin) or oxidized cellulose may be applied to the wounds (4). I still prefer the use of the gelatin sponge to oxidized cellulose because the latter produces local annoying discomfort for a period of 12 to 18 hours after operation has been performed.

At the conclusion of the operation the wounds and the rectum are inspected. The gauze sponge placed in the rectum at the beginning of the operation is now gently removed. This gauze had served as a barrier against blood clots which may cause postoperative tenesmus if not removed. If the biologic hemostatic agents just alluded to are not utilized then either a narrow strip of vaselized gauze or a small sized Penrose drain is left indwelling in the anal canal.

POSTOPERATIVE COURSE

The immediate postoperative convalescence is smooth and uneventful. Pain is controlled by the administration of an analgesic such as morphine sulfate or demerol in the same doses as given preoperatively. Parenteral

analgesics are not required in more than 40 per cent of these patients and do not require narcotic analgesics postoperatively. Acetylsalicylic acid 0.300 to 0.600 gram (5 to 10 grains) with or without phenobarbital 0.030 gram (1/2 grain) is prescribed routinely in order to avoid possible postoperative anxiety.

Catheterization is practiced whenever the patient has suprapubic pain and is unable to urinate in the standing position out of bed regardless of the time interval between catheterizations. It frequently is necessary to recatheterize patients within 2 to 3 hours at times even larger amounts of urine may be obtained at subsequent than at the initial catheterization. Catheterization is usually required in less than 25 per cent of patients. I do not share the opinion that spinal anesthesia is the sole cause of the patient's inability to urinate. Rather I attach more significance to the reflex inhibitory action produced by the operative manipulation of the tissues and their innervation which are in close anatomic proximity to the bladder neck.

Some time after a lapse of 48 hours the gauze packing or Penrose drain is removed. It is of course unnecessary to remove the hemostatic agents as these disintegrate or become absorbed spontaneously in 3 to 5 days. The wound is inspected daily.

A liquid or soft diet with a liberal intake of fluids is given during the first 24 postoperative hours. Thereafter a full house diet which is supplemented by several bananas daily is allowed. Liquid petrolatum in doses of 15 to 20 cubic centimeters ($\frac{1}{2}$ ounce) is given nightly until the wounds are completely healed. Usually a bowel movement occurs between the second and fourth postoperative day when the patient is discharged from the hospital.

A digital examination with the little finger is made between the fifth and the seventh postoperative days. Thereafter this procedure the index finger being used is repeated about once in 5 days to control the rate of healing and to break up any bridging that may occur. Complete healing of the wound usually occurs within 3 to 4 weeks with a resultant soft and pliable scar.

Occasionally probably the result of inadequate supervision there may develop dead space with low grade infection, resulting in a sinus or fistulous tract. This complication occurred twice in the series of operations which is presented herein.

SUMMARY

A successful surgical procedure for the extirpation of chronic anal ulcer as well as the preoperative and postoperative management is described and illustrated.

REPAIR OF HYPOSPADIAS WITH FREE INLAY SKIN GRAFT

FORREST YOUNG M.D., F.A.C.S., and JOHN A. BENJAMIN M.D., Rochester New York

IT has seemed to us in general that repair of hypospadias has been done at too late an age. Ideally repair of all congenital deformities is better done in early childhood and hypospadias is no exception. Not only is fixation of the physical deformity prevented but psychic difficulties are avoided if repair is done early.

It is probable that repair of hypospadias has been delayed because the small penis of early childhood is not well suited to the flap type of repair most generally used. For this reason we have reviewed the older methods with the idea in mind of selecting a principle of repair which could most nearly meet the requirements of first providing an adequate repair in few operative steps and secondly be practical early in childhood.

HISTORICAL BACKGROUND

The repair of hypospadias, we believe still remains a problem of considerable magnitude judging from the great number of procedures which have appeared in the literature. This is substantiated by an article by Cecil in which he lists 556 references and this list probably does not include all published works on hypospadias. But on analysis there are probably no more than seven surgical principles which have been reported in the past. These can be divided into two major groups: flap repair and free graft repair.

Chronologically these are

- A Construction of urethra with flaps
 - 1 Dieffenbach 1837-45
 - 2 Thiersch Duplay 1860-74
 - 3 Rochet 1899
 - 4 Bucknall 1907
 - 5 Ombredanne 1911
- B Construction of urethra with free graft
 - 1 Nové Jossierand 1897-1914
 - 2 Miscellaneous methods 1900-27

In deciding upon a method the surgical principles in the past have been thoroughly

From The Department of Surgery The University of Rochester School of Medicine and Dentistry and the Strong Memorial Hospital Division of Plastic Surgery and the Division of Urology. Added in part by the Dr. Henry C. Buswell Memorial.

reviewed. Modifications of these fundamental principles have been made but they are so numerous that they could only be considered in a more detailed treatment of the subject. They can be summarized as follows:

A Construction of urethra with flap—

1 Dieffenbach 1837-45 (translation). Building of a tunnel by transplantation. When no duct is in existence and the urine goes out of an opening in the back part of the penis then one makes a new canal of skin. One takes a fold of skin on each side of the penis and draws it together over the place where the urethra should be situated. Here one sews the edges of the skin folds together with a straight needle and a strong thread lengthwise in the manner of a tunnel. Thereupon one makes an incision on both sides of the penis through the skin in order to relieve the tension and finally one cuts the edges of the skin folds sewed together over the passage seam one after the other with a sharp scissors and draws the wound edge together by means of the continuous seam or a quantity of mounting pins (for insects) so that the epidermis will come in contact with epidermis. In order that the new canal may not interrupt the urine this is led away through the old opening with a catheter. If the building of this interior canal by means of skin drawn over is successful then it may be opened from the forepart and continued through the glans. If it has a crack, it will be healed by the bloody suture and then the still closed skin canal will be opened by means of a probe being drawn from the front to the back and a bougie drawn through the glans. The outer opening between the canal and the glans will be closed by spreading on *Tinct. cantharidum*. If however the glans is imperforate then one bores through it with a small trocar and draws into it the urethra. By means of a thick lead probe one tries to skin over the passage on the inside.

Dieffenbach (balanic hypospadias). The perforation of the closed glans is the least of these operations and the result is more sure. On the other hand this operation is doubtful when a longer canal is to be built. The operation proceeds in the following way. One braces the penis firmly and draws it in the same direction as the body then one takes a trocar suited to the age of the patient, which is provided either with a silver or lead pipe into the glans which provides constantly a dummy urethral opening on the under side of the penis along under the skin into the already existing canal of the urethra. Hereupon one draws the stylet out and leaves the lead pipe remaining. The treatment must be very aseptic, and especially the cold wrappings which will be wound around. One exchanges the lead pipe later with a

applied. A retained catheter is used to draw off the urine. The catheter holding the graft is removed in 8 days and 5 days later the passage of sounds is begun and continued for 3 weeks.

4. Bucknall 1907. Penis is drawn up over the abdomen and scrotum is pulled downward between

the thighs. Incision is made on either side of the urethral area and the scrotal raphe. The two longitudinal flaps thus developed are sutured in such a manner as to bring the raw surfaces of the penile flaps into contact with the raw surfaces of the scrotal flaps and the penile shaft is flexed on the scrotum.

Fig. 3. a. Urethral opening encircled by incision and dissected proximally. b. Incision prolonged longitudinally to frenulum. c. Dissection of fibrous tissue producing chord. d. Skin shifted from dorsum and closure in multiple Z-plasty to prevent lateral contraction. Urethral orifice displaced back and end of the shaft straightened.

The flaps are sutured together. A small rubber tube is passed down the newly constructed urethra to the bottom of the hypospadias meatus and this will maintain the urine. At the end of 4 days the catheter is removed and after 3 to 4 weeks the second procedure can be carried out and delayed for a longer time.

At the time of the second stage the penis and the urethra are dissected off the scrotum and the external skin edges are sutured together. Follow up in 3 cases, how good results 4 years, 2 years, and 3 years after operation.

5. Ombre Lanne 1911. The urethra is constructed by a pedicle flap of skin taken from the ventral surface of the penis behind the meatus to the posterior edge of which it is left unattached. This flap is turned forward by means of a purse-string suture so that its anterior end reaches the inferior surface of the glans where it forms the new meatus. The raw surface thus left is covered by buttoning the hood and bringing it down over the ventral surface of the penis. The total pedicle is divided later. This operation is said to obviate fistula formation but it leaves such a urethra the dribbling from which after micturition is likely to be very inconvenient for the patient especially when several tapes are required to bring the urethra to the end of the penis thus leaving a series of pouches each of which may retain a little urine.

6. Construction of urethra with free graft—

1. Nové Josseland 189, 1914. This method will be considered in detail with a translation of his first article "Treatment of Hypospadias New Method" found in *Proc. Nat. Ass. 189, 85, 105-200*.

Mr. Nové Josseland discusses a new treatment of hypospadias.

On August 18, 1895, he was called to attend a patient with hypospadias in whom he had previously

operated unsuccessfully with the Duplay procedure. He practiced the following operation. A transverse incision 2 millimeters long was made in front of the abnormal opening of the urethra then in the cutaneous cellular tissue under the skin. He introduced a full instrument which severs and separates the loose subcutaneous tissue while proceeding toward the base of the glans and so creates a canal under the side of the sound or rod (sic) a subcutaneous canal the anterior end of which opens, penetrating a little by little with a trocar.

This canal being established it becomes necessary to reinforce it internally with mucosa thus preventing it from closing on itself. For that purpose a piece of skin is taken from the thigh after the manner of Ombre Lanne, a piece of flesh dermoepidermic about 2 centimeters wide and of a variable length depending upon the amount of urethra which it is necessary to reconstruct. This graft is rolled around a No. 16 probe in such a way that the cutaneous surface is outward toward the probe, the growing surface is on the inside and the graft is fastened by two sutures at each end. Then is introduced the probe clothed in the cutaneous canal and the whole is kept in place by a convenient dressing.

At the end of 8 days the probe is withdrawn. The graft has taken perfectly so that there is a new cutaneous double canal of skin for the whole length. Daily catheterizations are started to prevent stricture which in the first few days may cause uneasiness. Now nearly 2 months after intervention the result seems to have been achieved. The canal has remained permeable by a No. 13 probe. During the first days it would admit only a No. 12. It is thus made supple and enlarged and it is hoped to achieve still more in this manner. During the first shaft at first remained very curved but

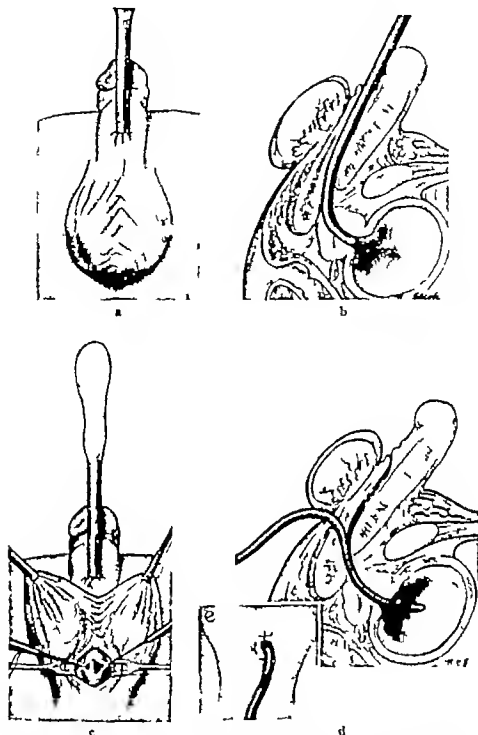

Fig 4. a and b First step in urethral reconstruction sound in place. c, Urethral opened rather high in perineum. d, Foley catheter in place. e, Wound closed snugly around Foley catheter

straightens out perfectly and it would appear possible soon to join the ends of the new canal with the old.

"The results obtained are therefore satisfactory and one may hope for even greater improvement. This is explained by the physiology of the Ollier Thiersch grafts at first they undergo a sufficiently strong retraction but later differing in this from scar tissue they become capable of being made flex-

ible and of yielding under the influence of traction methods.

"This method of treatment appears applicable to all varieties of hypospadias and it seems much preferable to all the other procedures in use today. The procedure of Duplay has had great success without doubt but ordinarily one does not obtain success except at the cost of repeated interventions and re-buffs are not rare. The difficulties of insuring perfect

Fig. 5. a Incision to free urethra. Note zigzag scar following chordee correction. b Tunnel made between skin and corpora, emerging through glans at mental depression. Urethra retracted laterally.

asepsis in this region the twitchings inflicted on a thin and fragile skin by erections explain why sutures so often break either partly or entirely. In spite of the precautions taken. All the methods using cut pieces of flesh on the rod are subject to the same criticism.

TABLE I—GIVES THE END-RESULTS REPORTED BY NOVÉ JOSSERAND IN 1914

Cure No.	Type of hypospadias	Age	Result
1	Penile-scrotal		Fistula followed 3 yrs
2	Penis	15 1/2	Good fistula small 4 1/2 years
3	Perifascial pseudobernaphoritis		Good fistula small 7 years
4	Penile-scrotal	15 1/2	Very good—followed 7 years
5	Perifascial	6	6 years—canal good—urine through fistula
6	Penis	13	Stricture
7	Scrotal	14	Good—7 yrs follow up
8	Penis	6	Good—7 1/2 years
9	Penile scrotal	5	Good—6 years
10	Penile-scrotal	7	Good—6 years
11	Scrotal	10	Good—6 years
12	Penile scrotal		Stricture
13	Penile	9	Good—15 1/2 years
14	Penis	Adult	Fistula—4 years
15	Penile (testis-scrotal)	15 1/4	Good—5 years
16	Penis	16	Stricture
17	Penile scrotal	4	Stricture
18	Perifascial	7 1/2	Good—8 months

Fig. 6. a. Free graft cut with dermatome from inner anteromedial surface of upper arm. b. Graft fixed in situ with dermatome cement. The 1 suture is to prevent rolling on introduction into tunnel.

"The scrotal flap has also been used with success, but because it should be of certain length it is exposed to mortification at least in part because of the comparative narrowness of the stalk.

In using the dermoepidermic graft one escapes all these inconveniences and one succeeds in an infinitely simpler manner in creating a canal to which one may give in the two senses, the dimensions one wishes. The observations of our patient demonstrates that the canal can persist and preserve its size; one is also permitted to hope that the tendency to contracture is practically conquered, it will become more and more flexible and will give a definitely perfect result."

2 Miscellaneous methods.—Some tissues used for urethral reconstruction: saphenous or some vein, Legueu (1911) ureter, Schmieden (1900) appendix, Weitz (1915) McGuire (1917) Axhausen (1915) vaginal mucosa Legueu (1918)

METHOD

In reviewing these past procedures it appeared that the principle most applicable to children as well as adults and one which could be done in the fewest steps with the smallest

Fig 7 a, Inlay graft in place. b, End of graft bearing catheter introduced into urethra. c, Graft and urethra approximated by suture.

Fig 8 a, Completed urethral reconstruction. Note suture lines do not coincide. b, Sagittal section showing relationships of catheter, ligatures, and suture lines.

possibility of multiple fistula formation was that of Nové Josseland. All of the repairs based on the principle of flaps involve numer-

ous operative steps are difficult to do on a tiny penis and frequently result in multiple fistulas which may be worse than the original

FIG. 9 (Case) a. An extreme pseudohermaphroditic deformity. The penis is completely adherent on its ventral surface. b. In this type of deformity the urethral orifice

remains free posteriorly in the perineum. c. Final result. Good urinary stream years after urethral reconstruction.

condition. It is probable that reconstruction of the urethra by a free skin graft has never been widely used first because urologists who mainly attend these conditions were not familiar with the principles of skin grafting and second because as originally described the possibility of contracture of the constructed urethra was ever present. It is of interest that Nové-Josseland described free graft repair of hypospadias in 1897. The graft he used was an Ollier Thiersch graft described and developed from 1872-86 by Ollier and Thiersch. It is well known that the thin Thiersch graft has a high percentage of contracture. Despite this Nové-Josseland was able to obtain good results in 9 of 18 cases which he reported in 1914.

The principle has been sporadically used without much modification. In general the plan has been to construct a tunnel with a free skin graft around a catheter from the site of the urethral ending out through the glans. This tunnel is then kept open by repeated dilations over a period of months. A good example of this without modification is the report by McIndoe in which the tunnel is dilated for some months. When it is finally judged past the contractile phase an attempt is made to join the urethra to the tunnel by a second

operation. As repeated dilations are difficult in small children the operation as usual done is more applicable to adults, which is evidenced by McIndoe's paper.

As we know skin grafts have greatly improved since Nové-Josseland's day so the more uniform grafts with less tendency to contract are now available. In addition, the Foley indwelling catheter as well as chemotherapy and antibiotic methods of controlling infection has been devised. All of these factors caused us to believe that it was feasible to attempt to construct the urethra in one step even in small children.

OPERATIVE PROCEDURE

Correction of chordee. As in all reconstructive procedures a method gradually evolves and our experience is no exception. The steps reported are those which we are now using. In brief we attempt to correct the chordee at one operation. This is done quite early if the patient is seen in infancy at about one year of age. In this respect most surgeons concerned with correction of chordee seem to agree. The advantages have been enumerated many times but for the sake of clarity they are (1) The chordee should be completely

Fig 10 (Case 2) a Conditions in which patient first presented himself. Chordee had been satisfactorily corrected elsewhere. b, Ventral view following urethral reconstruction. c, Reconstructed meatus in glans.

corrected before the urethra is reconstructed (2) Early correction of the deformity permits earlier urethral reconstruction (3) Growth proceeds more normally (4) Deformities in general are more easily corrected before they become fixed by growth

The objective of the first operation is to obtain a straight penis with lax skin on the ventral surface and if possible a plan which will prevent recontracture to any extent. In addition we have found that it helps prevent fistula formation when the urethra is constructed if the urethral orifice is off the midline (Fig 2b)

The first step is to dissect free the urethral opening. This dissection is carried proximally depending on the extent of contracture. In any event one must be certain to excise all of the fibrous tissue which holds the penis in the curved position. The urethra is freed by a circular incision and the dissection freeing it is done with a sound in place. When the proximal extent of the fibrous band is located the urethra is retracted out of the way with stay sutures and the band is dissected out beginning proximally. The skin is incised from the circular opening to the frenulum and dissected free on either side thus exposing the contracture. The dissection of the band proceeds

along the corpora cavernosa and must be quite close to it. In some instances Buck's fascia seems contracted and in order to secure complete straightening of the shaft must be cross-cut. At this stage the corpora cavernosa are plainly seen. The urethral orifice has dropped backward and it should be possible to hyperextend the penis without any ventral tightness. Once the deformity has been corrected one must attempt to prevent postoperative scar contracture causing a partial return of the deformity. If the skin of the penis is closed longitudinally as in the Heineke Mikulicz principle this is almost sure to happen. To avoid this the closure is staggered in multiple fashion by imbrication of triangular flaps. The most proximal of these is made so that the urethral opening is displaced from the midline. At the extreme distal end of the shaft skin may be deficient and if so skin is brought to the ventral surface from the hood. This is accomplished by making a dorsal slit in the hood, dissecting off and discarding the mucosal surface and transplanting the halves of the hood skin to the ventral surface of the shaft (Fig 3) (We have in some instances used the preputial mucosa for the urethral graft but in most cases there is not enough present for the full length of the urethra). The glans

TABLE II—ANALYSIS OF 10 CASES WITH IMMEDIATE AND LATE END-RESULTS

Case and unit number	Type of hypospadias	Age chordee corrected		Age urethra reconstructed	Results	
		Elsewhere	Circumcise		Immediate	Final

the graft and a stitch transfixes glans catheter graft, and abdominal skin. Thus the penis is held in hyperextension (Fig. 8).

The position on the abdomen facilitates the application of a compression dressing. Originally we immobilized the legs in an abducted position with plaster but we no longer do this as a simple compression dressing seems effective. In children the arms and legs are restrained. Originally we kept the graft bearing catheter in the penis for 14 days and the perineal catheter for 3 to 4 days longer. As we gained more experience this time has been gradually decreased. We noted that at 6 or 7 days there was often mucopurulent discharge at the glans meatus and similar discharge at the suture line on the shaft. Therefore we at present remove the catheter from the penis at 7 days and the indwelling perineal catheter on

the next day. The patient is kept in order to wash out the catheter. The catheter may then be inserted into the bladder if the penis does not close in 2 or 3 days.

DISCUSSION OF IMMEDIATE

It is now 7 years since we first reported our plan of hypospadias repair. In the 7 years we have completed 10 cases. The results can be summarized as follows: There are several other cases in which the chordee has been corrected but the urethra has not elapsed to allow for a normal erection. From these cases it is evident that the outlined for chordee repair is not satisfactory. In no case has there been an appreciable return of chordee after repair and nor has a significant

chordae been necessary. This statement applies not only to the penile type of hypospadias where the curvature is mild, but also to the severe pseudohermaphroditic deformities.

In the 10 cases in which the urethra has been constructed at one operation 3 have healed *per primam* with no leakage at any time and have voided through an adequate orifice in the glans penis as soon as the catheters were removed (Fig. 2).

One other case should probably be included as an excellent immediate result in the group above since in this instance a tiny fistula at the anastomosis closed spontaneously in 3 weeks. In 2 other cases a small fistula persisted at the anastomosis which had been operatively closed.

Three other cases have small fistulas at the anastomosis and are awaiting closure. We have found that it is not wise to attempt immediate closure of a fistula at the anastomosis because in some instances the fistula will close spontaneously in a few weeks and in others will shrink greatly over a period of 3 to 4 months. Actually these cases of fistula might be classed as good results by some observers because 2 of the 3 patients are voiding 95 per cent of the urine through the glans. In any event an attempt to close the anastomotic fistula must wait complete softening of the tissues in order to be successful.

In one instance we have had a persistent perineal urethrostomy fistula which had to be closed operatively. From these data it would seem that one can expect about 50 per cent excellent immediate results from the plan as outlined. It is worth noting that in no instance has there been a failure of the inlay graft taking. Furthermore fistula formation when it does occur is limited to the site of the urethral-graft anastomosis.

In the past we believe that the main reason for not using a free graft for urethral construction has been the fear of contracture and stricture. A follow up of our cases does not bear this out. At first we also had this lurking fear and dilated the constructed penile urethra frequently. We noted that this was often accompanied by bleeding and, of course considerable discomfort. Because it seemed that the continual trauma would predispose to

more scar tissue formation we abandoned frequent dilation and to our surprise found that the caliber of the stream in most instances actually improved. Evidently the urethral stream is sufficient dilation in those instances where it passes through the urethra. Since the urine comes through an anastomotic fistula, more frequent observation and passing of sounds to determine whether dilation necessary is advisable. The caliber of the stream is the best indication and on each follow up visit the patient should be observed voiding if possible.

We have now observed 2 cases for 5 years since construction of the urethra. Fortunately for our purpose one of these was a child 3 years old at the time of repair and the other an adult 39 years old. The child has maintained a completely satisfactory urethral stream and growth of the penis (Fig. 9). No tendency to stricture or for the chordae to return has been observed. This would seem to indicate that the graft has maintained a normal growth rate. The adult has developed no stricture and according to both him and his wife, sexual function is normal (Fig. 10).

Both of these patients have been endocoped. The graft in each instance bears a close resemblance to urethral mucosa. There was no hair present. At the site of the anastomosis a circular ridge was observed through which the instruments passed easily.

SUMMARY

A method has been reported which is completely satisfactory for chordae correction.

1. We have used a one stage operation for urethral construction in 10 cases. This is a modification of the two stage Nové-Jossard principle which utilizes a free skin graft for urethral construction.

2. Our experience has shown that this is a more satisfactory procedure than the generally used operations dependent upon flaps.

3. The advantages of this procedure are: It can be done successfully in about 50 per cent of cases in one operation. The urethra has a normal exit in the glans penis. This permits a more normal type of urinary stream. The orifice ending at the frenulum as it does in many flap operations does not afford this ad-

vantage The graft from the upper arm tends to eliminate the disadvantage of hairgrowing in the urethra which has often been reported as a complication following construction of the urethra from penile or scrotal flaps. We have seen no definite strictures occur Following flap operations it is not uncommon to have complete failure or multiple fistulas form. The poorest result in this regard when the urethra is constructed with a free graft is a fistula at the anastomosis of the graft and the urethra. This can be successfully closed at a later time

We believe that these results show that it is not necessary to use a two stage procedure as originally described by Nové-Jossierand. Finally we believe that most important of all the method is applicable to preschool age children and can be used for any degree of hypospadias.

CAUSALGIA

II The Signs and Symptoms with Particular Reference to Vasomotor Disturbances

HARRIS B. SHUMACKER, JR., New Haven, Connecticut, I. JOSHUA SPEIGEL, Chicago, Illinois,
and RICHARD H. UPJOHN, Salem, Oregon

ALTHOUGH certain aspects of causalgia had been described previously it remained for Weir Mitchell and his associates (7) to give a full account of this condition in a remarkably vivid and comprehensive manner. According to them the syndrome was characterized by the following features. It occurred following partial injuries of peripheral nerves. Although a few patients stated that the pain began at the moment of injury the authors expressed some doubt that this occurrence ever actually took place. The pain commonly began some time after the injury and generally during the period of healing of the wound. It was always burning in nature although it was sometimes associated with other types of pain. The intensity of the pain varied from trivial to an indescribable torture. It was felt predominantly in the periphery of the affected hand or foot, especially in the palm of the hand, the palmar surface of the fingers, and the dorsum of the foot. The painful extremity was exquisitely hyperesthetic to touch. As the pain continued the patients began to show evidence of irritability, anxiousness and emotional instability. Exacerbation of the pain generally occurred from touching the extremity, dependency, jarring the body, noises and emotional excitement. The pain was usually made worse by dryness and heat and was eased somewhat by wetness of the part and often by cold. The affected hand or foot commonly showed nutritive changes: glossy skin, diminished or absent growth of hair, abnormally curved nails. The skin was generally a blotchy

red color and was always warmer than that of the corresponding hand or foot.

With the passage of time and the study of numerous additional cases the essential features of this original description were repeatedly confirmed. In certain details, however, variations were encountered. It was recognized, for example, that not in all patients was the skin warm and pink. In some it was cold and pale. As the sympathetic nervous system became implicated in the treatment and presumably in the physiopathological mechanism of causalgia these vasomotor alterations assumed added significance. It was commonly stated that patients with causalgia exhibited either vasoconstriction or vasodilatation in the affected hand or foot.

It is our purpose to discuss the signs and symptoms and particularly the vasomotor status in a group of 90 cases which we have recently had an opportunity to study. The same group of cases are analyzed (10) in reference to the rôle of sympathetic interruption in treatment. The study includes only those patients who were felt to be suffering from major causalgia although several were atypical in certain aspects. One of them, indeed, as we shall discuss subsequently may perhaps actually not represent a true case of causalgia. We have excluded cases of minor causalgia, amputation stump pain, phantom limb pain, Sudeck's atrophy and related posttraumatic vasomotor disorders and the burning pain of paraplegia.

THE NERVE INJURY

The upper extremity was affected in 49 cases, the lower in 41. In Table I the distribution of nerve lesions is tabulated. The incidence of nerve damage is based upon carefully performed neurological examination both before and after relief of causalgia. It must be

From the Vascular and Neurosurgical Centers, the Mayo General Hospital, Galesburg, Illinois; the Department of Surgery, the Yale University School of Medicine, New Haven, Conn., and the Department of Neurosurgery, the University of Illinois College of Medicine and the Michael Reese Hospital, Chicago, Illinois. Aided by a grant from the Office of Naval Research, the United States Navy.

emphasized that such examinations carried out before the pain has been eliminated are notoriously misleading the extent of nerve dysfunction often appearing greater than is actually the case. When the involved nerves were explored, the condition found at operation is taken into consideration.

It will be seen that in 34 of the 41 cases in involving the lower extremity the sciatic nerve was injured while in 5 of the 7 remaining cases either the peroneal or tibial nerve was damaged. When the sciatic nerve was injured the peroneal component was sometimes affected alone in other cases only the tibial component, and in still others both divisions. Altogether there was evidence of partial tibial paralysis in 27 cases while in 7 the tibial nerve was clinically completely paralyzed. Similarly the peroneal nerve was partially paralyzed in 16 instances while it appeared completely paralyzed clinically in 14.

In 14 cases the brachial plexus was injured. All cords of the plexus were traumatized in 9 instances the median and lateral cords in 4 and in 1 case only the origin of the ulnar nerve. In 11 cases the median radial and ulnar nerves were damaged and in the 24 remaining cases of causalgia of the upper extremity the median radial or ulnar nerve or various combinations of two of them. It has generally been stated that the median is a most commonly affected nerve in causalgia in the upper extremities as is the sciatic in causalgia of the lower extremities. Altogether the median nerve was partially paralyzed in 34 of our cases and apparently completely paralyzed in 5. Similarly the ulnar nerve was partially paralyzed in 29 and completely in 8.

In 11 instances the affected nerves of the causalgic extremity appeared clinically to be completely paralyzed. Seven were cases of sciatic injury in 1 the entire brachial plexus was paralyzed and in the 3 others the nerve involved was the saphenous the tibial and the median. When such lesions were explored neuromas in continuity were found and electrical stimulation failed to demonstrate any motor function. It must be emphasized however that we have no proof that a few intact sensory fibers may not have traversed the neuromatous mass. Our series contains no

TABLE I — DISTRIBUTION OF NERVE LESIONS IN CAUSALGIA

Nerves affected	No. of cases

Peroneal	2
Tibial	3
Total	90

cases of complete paralysis in which widely divided and completely separated ends of the nerve were demonstrated at operation. All that can be said is that causalgia did occur in certain patients with apparently complete nerve lesions.

PAIN

In regard to the question which Mitchell, Moorehouse and Keen raised concerning the onset of pain at the moment the wound was incurred we found that our data were somewhat unreliable. A number of individuals stated that their pain began immediately but on more careful questioning it was always evident that their memory for such details during the first few hours or even days was often hazy. At any rate 50 said their pain began immediately, 23 from the first to the eighth day, 9 during the second or third weeks, 3 from 1 to 2 months and one, 4 months after injury. No data concerning onset of pain are available upon 4 cases.

The pain was described as burning in character by all save 4 patients. Only 40 of these 86 patients however had burning pain only. Pins and needles sensations were described by 9 patients, tingling by 17, stinging by 2. Two patients said they had knife like pains, 3 cutting, 8 shooting, 1 stabbing, 3 shock like, 1 sticking pain. Throbbing pain occurred in 7. Six had a sense of crushing, 2 of intense pressure, 2 of squeezing and 1 of mashing. Pulling, tearing, breaking, drawing, boring or buzzing sensations were complained of by another 6 individuals. Thirteen complained of a deep aching pain.

In contrast to the great frequency with which some relief of pain by wet applications was recorded in the original account of Mitchell and in other reports we found that numerous individuals had not experienced alleviation from anything at all indeed this was the case in 64 of the 90 patients. Twelve patients obtained slight or moderate relief from wet cold applications to the affected limb. They kept their hand or foot constantly wrapped in cool wet cloths. In all of them the painful hand or foot was warmer than the contralateral one. Three stated that cold weather gave some relief only in 1 was the extremity warmer than the other. Two individuals thought they obtained some alleviation either from local cooling or warming of the hand. Two thought warmth was of some help and 5 thought warm wet poultices eased the pain somewhat. In only 4 of these 7 patients was the temperature of the affected limb lower than that of the contralateral one. One patient said oiling of his hand gave a little relief and 1 found that he was helped by blowing upon his hand.

On the other hand all of the patients enumerated one or more factors which aggravated the pain. Almost without exception the pain was made more intense by use of the part and in every patient by touching or tapping the affected hand or foot. Most of them complained of increase in pain when the limb was made dependent. All of them guarded their injured limb with great care and all of those with injury of an upper limb kept the arm adducted, the forearm flexed and most of them supported the forearm with the other hand. They could be approached and examined only after urgent and gentle pleading and reassuring and even then examination was rendered unsatisfactory because of their great dread of having the extremity touched. In many patients exacerbation of the pain resulted from noises emotional excitement, and the slightest farring such as that induced by the closing of a door or the walking about of an individual in the examining room or even in the hallway outside. Unfortunately our records are incomplete in regard to this point in some instances. Such factors caused increase in pain rarely in the milder cases but

very commonly in the more severe ones. In addition to aggravation of pain from touching of the part 6 complained that continued pressure had a similar effect. One patient was made much worse by hunger. In 10 patients the pain was made worse by cold in 6 of them the affected hand or foot was cooler than the other. One who said moderate cold brought relief noted an increase in pain from intense cold. Three said either heat or cold intensified the pain. In 9 patients exacerbation from warmth was noted in 7 of them the hand or foot was warmer than the contralateral one. One patient who obtained some relief from wet warm applications was made worse by dry warmth. One said his pain was made more severe by wet weather 1 by dryness, and 1 by any wet applications.

It will be noted that 13 of the 15 patients who noted relief of pain from cold had relative increase in skin temperature of the affected limb and that a majority of those whose pain was helped by warmth had relative decrease in skin temperature of the injured extremity. Conversely a majority of those whose pain was aggravated by cold had relative vasoconstriction and of those made worse by warmth relative vasodilatation. It is perhaps significant however that there were exceptions.

The pain was localized in the hand or foot in all instances in a few it also extended to the forearm or leg. It was commonly limited to or was more intense in the distribution of the injured nerve but in numerous instances other parts of the hand or foot were also affected. As was true in the patients described by Mitchell and his associates the pain in the hand was generally felt in the palm and palmar surfaces of the fingers. In contrast to the experience however we found that the sole of the foot was very frequently the site of intense pain. Most of the patients described the pain as superficial but many also described it as deep.

In another article (10) we have analyzed the results of procaine sympathetic anesthesia in 83 patients and of permanent sympathetic interruption in 57. In all save 1 atypical case temporary complete or nearly complete alleviation of pain followed procaine anesthesia while in 21 patients a satisfactory permanent

TABLE II—DIGITAL SKIN TEMPERATURE STUDIES IN PATIENTS WITH CAUSALGIA IN WHOM THE AFFECTED AND CONTRALATERAL EXTREMITIES WERE ABOUT EQUAL IN TEMPERATURE

Case No.	Room temperature	Skin temperature of affected extremity			Skin temperature of contralateral extremity			Arterial occlusion	Subjective estimate of temperature of affected limb as compared with that of contralateral limb

relief was brought about by one or more procaine blocks. In all save the one case in which little relief of pain followed sympathetic block, definite diminution in pain was achieved in the 57 cases treated by sympathectomy. In many the relief of pain was complete or nearly so.

VASOMOTOR STATUS

In all patients an effort was made to evaluate carefully the vasomotor status. An inquiry was made into the state of vasomotor tonus before the injury into the subjective sensation of warmth or coldness and of sensitivity of the hand or foot to cold during the present illness into any alterations of color or sweating into the presence of edema. It was not always possible to perform all the circulatory tests desired, often the patient's overwhelming fear of aggravation of pain could not be overcome sufficiently to obtain his permission or co-operation. For example, we

were commonly unable to obtain oscillometric studies and could never do such tests as reactive hyperemia. We were not equipped to do digital plethysmography or venous occlusion plethysmographic studies of blood flow in the limbs. Notes were made upon color, temperature, sweating, venous filling time when possible and edema. The effect of sympathetic procaine block upon pain, color and temperature was noted in 83 patients.

One patient gave a history of abnormally low vascular tonus, 11 of high vascular tonus and the remainder apparently had had normal vascular tonus before the injury. Since the onset of causalgia, 12 patients said the injured hand or foot was warmer than the contralateral one. Twenty-seven said the hand or foot was colder than the other. The other 51 patients thought there was no difference in temperature or in a few cases stated that the involved hand or foot was sometimes warmer and sometimes colder than the other.

Upon examination the affected hand or foot was pinker than its mate in 30 patients. Often this increased color was of a mottled spotty nature and in 8 instances was associated with a mild cyanotic tinge. The hand or foot was cyanotic in 29 cases and pallor was noted in 5 instances. In the rest there was no apparent difference in color between the injured and uninjured hands or feet. Our records contain notes concerning sweating in 57 cases. In 21 the affected hand or foot did not sweat in 5 sweating was diminished in 23 sweating was increased and in 8 patients there was no difference in sweating in the two hands or feet. In some patients the skin appeared to be relatively normal in texture. In almost half of the remaining cases it was dry and scaly and in the other half shiny thin and glossy. Stiffness of joints and abnormal curving of the nails were present in some especially those with glossy skin. In a number of cases the growth of hair was altered in most of them it was diminished in a few increased. The peripheral pulses were not significantly altered except in those patients in whom a major artery had been injured and ligated or occluded by thrombosis. In about 35 per cent of the patients venous filling time was about the same in the two hands or feet in about 25 per cent it was relatively increased in the affected limb while in the remainder it was decreased.

In 54 cases accurate skin temperature studies were made. In 19 (35 per cent) the digits of the affected hand or foot were about equal in temperature to those of the opposite extremity (Table II). Over half of the patients had the subjective feeling that the injured limb was colder than the other. In 10 (18.5 per cent) the causalgic hand or foot was distinctly colder (Table III). It is of interest that in 4 of the 10 patients a major arterial stem in the injured limb had been obliterated by traumatic thrombosis or had been ligated. Several of the patients had real sensitivity of the hand or foot to cold. Four of the 10 patients thought the affected hand was colder than normal, 3 that it was warmer and 3 thought that the two hands or feet were equal in temperature. In 25 (46.3 per cent) patients the digital skin temperature of the injured limb was distinctly higher than that of the other (Table IV). Nine of the 25 patients thought the hand or foot warmer than normal, 6 thought it colder than the contralateral one, and 10 noted no difference in temperature of the two hands or feet. Examination of the data recorded reveals that only in a few instances was the skin temperature in the range of maximal vasodilatation. In Table V skin temperature measurements in 13 of these patients before and after sympathectomy are listed. It will be seen that in nearly every case a distinct increase in warmth occurred after operation. It is obvious then

that vasodilatation in our cases was relative and not maximal.

In Table VI some oscillometric studies are tabulated. No cases are included in this table in which the circulation was altered by thrombosis ligation aneurysm or arteriovenous fistula of the main artery to the extremity. It is seen that in only 2 cases was the oscillometric reading distinctly greater in the affected limb. In half the cases the values were not significantly different in the two extremities while in 8 cases they were considerably less on the side of the injury. These findings are perhaps unexpected in view of the fact that in three-fourths of the patients the affected hand or foot was distinctly warmer than the other and

in only 1 was it colder. Indeed the finding of equal or reduced oscillometric readings in a limb in which some degree of skin vasodilatation exists as a consequence of peripheral nerve involvement might seem inexplicable. We have however often observed a marked increase in oscillometry after sympathectomy in extremities in which elevation of skin temperature had already existed as a result of somatic anesthesia. These observations suggest that interruption of sensory nerves may bring about surface vasodilatation without necessarily causing full dilatation of the larger arteries. It is entirely possible that on occasion certain irritative reflex phenomena may be present which tend actually to result in

relative constriction of the major arteries while at the same time anesthesia or hypesthesia from peripheral nerve injury results in relative skin vasodilatation.

OTHER OBSERVATIONS

There were associated vascular lesions in 23 patients. In 15 cases the main artery of the extremity had been injured and had either thrombosed or had required ligation. The brachial artery was so affected in 9 cases, the axillary in 3, the subclavian in 1, the femoral in 1, and the radial and ulnar in 1. In 8 patients an aneurysm or arteriovenous fistula had resulted and had either already been treated by some method requiring ligation of the affected artery or was so treated by us. In 1 patient there was an arteriovenous fistula of the brachial vessels and in 1 a fistula of the femoral vessels. Aneurysms involved the brachial artery in 2, the popliteal artery in 2, the axillary in 1, and the profunda femoral in 1 case. Atrophy and contractions tended to be more severe in the cases with arterial

*No cases are included in which the circulation was shown by test bones, heat, aneurysm, or arteriovenous fistula of the main artery of the extremity. The oscillometric readings recorded were made in cases of involvement of the upper extremity and in the cases of involvement of the lower extremity.

occlusion than in those with good arterial circulation.

In 22 patients there were associated fractures. In 10 patients there was a fracture of the humerus and in 7 of the femur. In the remainder there were fractures of the pelvis in 1, the tibia in 1, the radius and ulna in 1, the humerus radius and ulna in 1. In most of the patients the fracture was infected and also ununited. These patients subsequently required further operative treatment. Not infrequently the bone grafting and the arthrolysis or neurolysis were carried out in a combined operation.

Osteoporosis was commonly present in the bones of the affected hand or foot but was not strikingly different from that found in similar cases of nerve injury and disuse not associated with causalgic pain.

DISCUSSION

Most of the observations made by Mitchell, Moorehouse and Keen concerning the signs and symptoms of causalgia have been substantiated in subsequent reports and are confirmed by the studies which we have made. Little has been added to their careful notes upon the pain its exacerbation and its effect upon the general physical and emotional state of the individual. In certain respects however there are discrepancies between their original findings and later observations. Their doubt that the pain ever commenced immediately following wounding is not borne out by the answers of our patients and the same was true in regard to a few of their own patients. Numerous patients said the pain began 'immediately' in our series and in those recently reported by others (9 11). One can of course question the reliability of memory for details during such a trying period. In all of the patients of Mitchell and his co-workers the pain was described as burning an observation so constant as to lead Mitchell subsequently to coin the term causalgia (6). In 86 of our 90 patients burning pain was present but 4 (4.4 per cent) did not describe any burning pain. About 10 per cent did not describe their pain as burning in Kirklin Chenoweth and Murphy's series. Rasmussen and Freedman found no burning in 45 of their 100 cases. They state that the clinical picture of these 45 patients was 'nearly identical' with that in the others. They do say however that Homans' cases of minor causalgia were similar to some of the 45. In our 4 cases without burning pain the symptomatology signs, and response to treatment were otherwise entirely similar to the rest. It would seem therefore that occasional individuals with true causalgia have no burning pain or describe it as pain of some other sort. With regard to the location of the pain subsequent observations have confirmed the original statements of Mitchell and his associates though specific observations such as its rarity on the sole of the foot, have not been substantiated. The transient partial relief of pain from wetting the part which they described has been commonly observed in other series of cases though generally in a smaller percentage of patients. Some of our

patients obtained such relief but many did not.

Mitchell Moorehouse, and Keen originally found causalgia only in cases of partial nerve injury. It has subsequently become apparent that causalgia may occur when the nerve damage is apparently complete (1 3 5 8). In 11 of our patients the nerve injury was clinically complete. When these lesions were explored neuromas in continuity were found and in none of our cases was the nerve found divided with widely separated ends. It is interesting that neurothraphy did not result in relief of pain except in 2 patients.

The glossy fingers tapering curving of the nails which occurred so commonly in the original account was present in a striking degree in only a small percentage of our patients. Such changes were more frequent in association with impaired vascular supply to the extremity.

The vasomotor status of the affected limb was often but not invariably altered. In about one-third there was no significant difference in temperature of the two hands or feet. In 18.5 per cent the causalgic hand showed evidence of vasoconstriction and in 46.3 per cent of vasodilatation. The vasoconstriction was intense in only a few however and the vasodilatation was rarely full. Some of the patients in whom the skin temperature was increased had no significant increase in oscillometric readings. The commonest alteration in color was a spotty redness of the part, or cyanosis of varying degree. Pallor was noted in a few of those with vasoconstriction. It was evident from our study that the patient's subjective estimate of the temperature of the limb was a poor index of the actual state.

When cases of vasoconstriction of causalgic limbs were first noted it became evident that the original finding of increased warmth was not a constant accompaniment of this syndrome. Most of those who have studied causalgia in recent years have reached the conclusion that this disorder is associated with some vasomotor alteration which may be manifested either as vasoconstriction or vasodilatation. It would appear from our studies that a considerable number of cases are associated with no significant vasomotor alteration and that

when such changes occur they are frequently not of extreme degree. Furthermore study of the vascular responses in numerous cases of peripheral nerve injury without causalgia reveals similar vasomotor changes to those noted in causalgic limbs. In such patients increased warmth of the injured hand or foot occurs very commonly and diminution in skin temperature in some. It would seem that the physiopathological explanation of the pain of causalgia must take into account the fact that the pain may occur in the presence of increased, decreased or relatively normal vasomotor tonus as well as the fact that altering the vascular tone by any means other than by sympathetic interruption results in no effect upon the pain in the majority of cases.

Kirklin, Chenoweth and Murphy have recently re-emphasized the constant feature of accentuation of pain in causalgia by certain disturbing features in the patient's environment. Our experience is in entire agreement. Donpe, Cullen and Chance have proposed relief of pain by sympathetic anesthesia as an essential characteristic of causalgia. In a survey of recently reported experiences with over 300 cases of causalgia, we can find nothing to suggest that any true case of causalgia has failed to respond to sympathetic block by a period of complete or nearly complete subsidence of pain. In our own experience such relief was obtained in all cases except one (10). This patient had a complete neuromatous involvement of the entire brachial plexus following an avulsion injury, thrombosis of the subclavian artery and fracture of the humerus. His pain was atypical in its wide distribution, the severe mashing aching burning and squeezing pain being felt throughout the hand forearm and the distal third of the arm. It was not affected by temperature but was worse with movement touching the part and with wet applications. Nothing brought amelioration. The circulation was precarious, and sympathectomy was performed largely for this reason; it afforded no more alleviation than the block. We have included this case in our survey particularly because it represents

the only real failure from sympathetic interruption. It is our feeling, however, that relief of pain by sympathetic block is an essential feature of true causalgia and in this respect the case should be excluded.

SUMMARY AND CONCLUSIONS

The signs and symptoms of causalgia are analyzed in a series of 90 cases. In the light of this study and available data in the literature it is concluded that the following features are an essential part of the clinical picture of major causalgia. It is characterized by constant spontaneous pain following injury of a peripheral nerve or nerves, generally but not invariably burning in character but also associated with other types of pain. The pain is most intense in and is usually limited to the distal portions of the extremity and particularly to the peripheral sensory distribution of the affected nerves. It is exacerbated by certain stimuli and is relieved completely or nearly so during adequate sympathetic or cocaine anesthesia. The associated nerve injury is generally incomplete but may be complete. The vasomotor status of the affected hand or foot may be relatively normal or may show evidence of varying degrees of vasodilatation or less often of vasoconstriction.

DICUMAROL PROPHYLAXIS AGAINST VENOUS THROMBOSIS IN WOMEN UNDERGOING SURGERY

GEORGE VAN S SMITH, M.D. F.A.C.S., and WILLIAM J MULLIGAN M.D.,
Brookline, Massachusetts

ON January 31, 1943, the use of dicumarol was begun at the Free Hospital for Women with the purpose of preventing postoperative complications from intravenous thrombosis. The drug was administered to women undergoing major and vaginal plastic surgery. The major surgery comprised for the most part pelvic procedures but included a goodly number of operations on biliary, intestinal and urological parts of herniorrhaphies and radical mastectomies. Most patients receiving the drug were over 40 years of age. It was given to women under 40 with the following as indications: obesity, varicose veins, a history suggesting previous thrombosis and cardiovascular disease. During the 4 year period ending January 31, 1947, 2,353 patients were treated prophylactically with dicumarol. This paper is presented as a progress report.

Dosage schedule. On the assumption that intravenous thrombosis might begin during or just after surgery, dicumarol was given preoperatively for the first 3½ months of this study in doses of 200 to 400 milligrams during the 40 hours preceding operation. No difficulties were encountered in the matter of hemostasis during operations or as regards the development of postoperative hematomas. A higher than usual incidence of postoperative thrombosis in leg veins ensued, the complication occurring 6 to 15 days after the taking of the drug without serious consequence. The impression was gathered that when the effect of dicumarol disappears, the blood of some women seems to acquire a greater tendency to clot intravenously. That a few thrombotic complications have since developed in dicumarol treated patients after their discharge from the hospital strengthens this impression.

Because of this early experience a change to postoperative administration of the drug was made.

For the next 22 months dicumarol was prescribed 30 to 48 hours after operation and again 5 days later. A third dose was administered after an additional 5 days if the patient was still in bed. The 5 day interval was chosen on the basis of studies of prothrombin times (*vide infra*). The first 2 doses were arbitrarily set at 200 milligrams for patients weighing more, and 100 milligrams for those weighing less than 60 kilograms. The third dose was 100 milligrams. The schedule was interrupted upon the occurrence of a hemorrhagic complication or if the prothrombin time was found to be 70 seconds or over 4 or 5 days after the preceding dose.

Because of a small series of secondary vaginal hemorrhages following plastic procedures late in the winter of 1945 and associated with unusually prolonged prothrombin times these doses were all reduced to 50 milligrams. The death of a patient from pulmonary embolism early in May, 1945, 2 days after receiving her second 50 milligrams of the drug brought about a return to 100 milligram and 200 milligram doses, the latter however being much less frequently prescribed. Furthermore since patients were getting out of bed sooner during 1945 and 1946 the third dose was only occasionally given. Although the majority of patients treated between May, 1945 and February, 1947 have taken 100 milligrams 28 to 40 hours after surgery followed by a similar amount 5 days later, a fair number of patients have received these amounts the night before operation and 5 days later. In these no greater tendency to bleed during operation has been noted.

Prothrombin time. The dosage schedule employed in this clinical trial was planned with the purpose of prolonging the prothrombin

From the Free Hospital for Women, Brookline, Mass., and the Department of Gynecology Harvard Medical School, Boston, Mass.

TABLE I—INCIDENCE OF POSTOPERATIVE THROMBOTIC COMPLICATIONS

Number of patients	Number of thromboses	Incidence	Number of nonfatal emboli	Incidence	Number of fatal emboli	Incidence
1. 1917-1934, incl—1,458 ward patients					23	1.56
2. 1937-1939, incl—6,54 private patients						1.20
3. 1937-Jan. 30, 1943, incl—1,466 ward patients	38	90	28	14.15		6.56
4. 1940-Jan. 30, 1943 incl—1,855 private patients	9	95	8	26.1		9.04
Totals before dicumarol	37	90	31	43.2	66	28.4
5. Jan. 1, 1943-Jan. 30, 1947 incl—1,000 ward patients, 50 received dicumarol	26	30	16	36.30	3	18.75
6. Jan. 31, 1943-Jan. 30, 1947 incl—1,797 private patients, 97 received dicumarol	6	3	6	6.3		3.99
Totals during dicumarol	42	33	22	33		30.77
7. Jan. 31, 1943-Jan. 30, 1947 incl—total of 5, 53 received dicumarol		33		33		31.7

*The number of thromboses includes those who developed embolism, both nonfatal and fatal.

time in the majority of patients at the same time avoiding hemorrhagic complications and compared with the amounts of dicumarol used by others in the actual treatment of thrombosis was conservative. Because of the limitation of technical help imposed by exigencies of war time and to avoid the discomfort of repeated venipuncture the intention was to carry out this study with a minimum of prothrombin determinations. Early in the series sufficient determinations were made to show that doses of 100 milligrams of dicumarol cause the prothrombin time to be prolonged significantly in most patients by the second day after ingestion this effect lasting 2 to 5 days. Prothrombin times were determined frequently during the early months of this investigation and then sporadically until the late summer of 1944 chiefly in those having thrombosis or hemorrhage. Subsequently more frequent determinations were made and it gradually became a routine to have the prothrombin time performed before the second dose of dicumarol was prescribed. Failure to perform the test daily on all patients resulted in too low dosage for those who developed thrombosis and in failure to detect the few who because of apparent sensitivity to the drug developed unusual or aggravated hemorrhagic complications. It has also become routine to delay the second dose of dicumarol for 3 days if the prothrombin time is less than 35 per cent of normal or under the same circumstances to

omit the second dose entirely if the patient is ambulatory.

Results and comments. In Table I the incidence of postoperative thrombotic complications among ward patients is compared with that among private patients both before and during the dicumarol era. The study covers 41,001 patients operated upon 31,950 before and 9,051 during the 4 year period of prophylactic dicumarol administration. About 38 per cent of the operations performed at this hospital are major; about 35 per cent consist of major pelvic surgery and about 30 per cent are hysterectomies. For example of the 1,797 patients operated upon in 1946 885 underwent major surgery and of these 716 had hysterectomies. The number of thromboses given in the table includes those who developed embolism, both nonfatal and fatal. Under the heading of thromboses are included cases of superficial and deep phlebitis of one or both lower extremities as well as pelvic phlebitis. By the term phlebitis both phlebothrombosis and thrombophlebitis are meant.

Seven of the thromboses listed in Sections 5 and 7 of Table I occurred in patients who had received dicumarol before operation only. As stated under Dosage schedule it is our impression that these patients, most of whom were not ambulatory when the effect of the preoperative dicumarol had worn off had become more prone to the development of thrombosis, perhaps as a result of an over

production of clotting factors in the response to the drug. None developed pulmonary complications.

Since 1930 various means have been employed in an effort to reduce postoperative thrombosis at this hospital viz raising the foot or the head of the bed for one to 4 days after operation giving thyroid extract encouraging activity in bed and maintaining a better fluid balance. Yet thrombotic complications were not reduced. In fact in 1942 there were 36 cases of thrombosis the highest incidence in years. Perhaps the decreased incidence of thrombosis and pulmonary complications since 1942 (Table I, Sections 5 and 6) may be laid to even greater awareness of the medical and nursing staffs toward measures considered possibly effective in the prevention of thrombosis. The use of abdominal binders was discontinued. Postoperative distention has been more actively combated by gastric and intestinal intubation. Fluids and vitamins B and C have been more freely given parenterally. Deep breathing and leg exercises have been encouraged but not enforced. The more general employment of antibiotics by preventing or ameliorating major and minor sepsis has undoubtedly had some influence against thrombosis. Finally during 1945 and 1946 patients have been getting out of bed earlier between the third and eighth postoperative day but real early rising has only occasionally been instituted. Thus the improvements shown in Table I may not be attributed unequivocally to the use of dicumarol. On the other hand they seem sufficiently impressive to warrant the conclusion that dicumarol was a factor in their achievement.

That there were no fatalities from pulmonary embolism among the private patients operated on between January 31 1943 and January 31 1947 (Table I Section 6) although only 197 (selected cases of the senior author's) had dicumarol, statistically appears to weaken any proposition that the prophylactic use of the drug in ward patients was effective. The impression prevails among many clinical investigators however that postoperative thrombotic complications occur more often in ward than in private patients. This

TABLE II—COMPLICATIONS AND DICUMAROL

Type	943-1944 No. cases	945-1946 No. cases	Total
Hematemesis			
Hematuria	8		
Vaginal hemorrhage	14	6	20
Hematemesis and vaginal hemorrhage			
Subarachnoid bleeding			
Total	0	7	26

Impression is supported by the figures in Table I except as regards nonpulmonary embolism which occurred often in private than in ward patients before and during the dicumarol study notable that there was no striking decrease in the incidence of nonfatal embolism in patients such as took place in the ward patients during the time dicumarol was prescribed (Section 6 Table I). The 61 patients with nonfatal embolism were fully treated either by heparin and interruption of the femoral veins these measures in all probability being effective in preventing at least 1 or 2 fatalities.

The 1 fatality from embolism among receiving dicumarol prophylactically (Section 7 Table I) occurred 2 days after the two 50 milligram doses of the drug which retrospect were too conservative. One patient in this group who developed embolism was refractive her prothrombin time being normal 3 days after a 100 mg dose.

Complications from dicumarol. The complications were hemorrhagic. No side effects were observed. In Table II listed the hemorrhagic complications attributed at least in part to dicumarol because the unusually prolonged prothrombin time determined in these cases. The vaginal hemorrhages occurred in patients who had had pelvic operations or total hysterectomies or both. Although the drug is believed to have prevented vaginal hemorrhage in the cases listed we would point out that the incidence of operative vaginal hemorrhage during years before the dicumarol experiment was

same as that both in the dicumarol group itself and in all patients operated on between January 31 1943 and January 31 1947. The reduction of hemorrhagic complication in 1945 and 1946 however when 200 milligram amounts of dicumarol were much less often prescribed and when the giving of the second dose was contingent upon a prothrombin time not less than around 40 per cent of normal is noteworthy. Hemorrhage associated with an unusually prolonged prothrombin time has been satisfactorily treated by menadione bisulphate in 40 to 64 milligram amounts administered parenterally and repeatedly and fresh whole blood transfusion—along with resuture when of vaginal origin.

The patient who developed a subarachnoid hemorrhage died. The following is an abstract of her record.

Mrs. P. MacL. (Hospital No. 33473) aged 46 years, weight 127 pounds was admitted on August 10, 1944. On preoperative examination her blood pressure was 130/80 and the only abnormal cardiovascular findings were a soft apical systolic murmur and moderate varicosities of the veins of both legs. On August 13 1944, complete hysterectomy and bilateral salpingo-oophorectomy were performed for a 6 inch right ovarian cyst. She received 100 milligrams of dicumarol 34 hours after operation and again 5 days later. Prothrombin time was not performed. Convalescence was uncomplicated and she was discharged on August 24. At 6 o'clock the fol-

lowing morning after returning to bed from the bathroom she experienced severe occipitofrontal headache accompanied by tingling sensations in fingers and toes. There followed intermittent vomiting.

She was readmitted on August 25. Nothing abnormal was found on general physical and neurological examination except for stiffness of the neck. No localizing signs were elicited. Lumbar puncture released amber colored fluid under pressure. By August 31 there was much less headache and vomiting had ceased. The prothrombin determination however on that day 13 days after the last ingestion of dicumarol, was 36 per cent of normal indicating idiosyncrasy to the drug. The ingestion of 7 grams of acetylsalicylic acid during the previous 6 days probably had contributed to the prolonged prothrombin time. She was transferred to the Neurological Service of the Massachusetts General Hospital. On September 5 her condition was reported to be good, but 9 days later death was caused by a second subarachnoid hemorrhage. It would seem that if dicumarol had played a part in her demise death would have occurred at the time of the first hemorrhage.

CONCLUSION

The use of dicumarol in 2,353 selected patients out of a total of 9,051 operated upon during a 4 year period appears to have contributed to a considerable reduction of the incidence of postoperative thrombotic complications without in itself causing a distressing amount of trouble.

At autopsy multiple small aneurysms of the circle of Willis were revealed along with organizing and recent hemorrhage.

CARTILAGINOUS TUMORS OF THE HAND

JOHN G SHELLITO M.D. and MALCOLM B DOCKERTY M.D.,
Rochester Minnesota

CARTILAGINOUS tumors of the hand grow in on or in close association with the bones of the hand and wrist. These tumors are clinically important because to a great extent they occur on or in two of the most important organs the hands. In the hand these tumors (1) interfere with function (2) are a source of potential malignancy and (3) are unsightly for cosmetic reasons (Fig 1).

It was found on reviewing the literature that all too often cartilaginous tumors are lumped together under the heading osteochondroma and the suffix sarcoma added to denote malignancy. It was discovered that it is correct on the basis of pathology to divide these tumors into two types the enchondroma or chondroma and the ecchondroma.

HISTORICAL DATA

As early as the time of Virchow the distinction between enchondromas and ecchondromas had been made and mentioned in the German literature.

Virchow stated that an enchondroma was an enlargement of a cartilaginous rest in the bone marrow and in other sites where cartilage was not normally found. He called an ecchondroma a perichondroma and stated that these cartilaginous tumors occurred at the edges of bone were usually located near the epiphyses of long bones and came from an overgrowth of permanent cartilage.

Enchondroma Geschickter (10-14) and many others have been of the opinion that these tumors are the result of cartilage rests which represent supernumerary articular cartilages. This opinion is supported by the fact that these tumors occur in a location where many small joints develop such as the hands

feet and vertebrae. These cartilage rests or islands form the central chondromas. Virchow also stated much this same hypothesis and it is supported in the literature by Bell (2) who said that chondromas may arise from temporary osseous cartilage and from fetal cartilaginous rests. Bell (1, 3) also stated that they may arise from some other connective tissue by metaplasia. Goddu, Raisch, Boyd, Ewing and Gatewood supported the cartilage rest hypothesis of origin or that of a primitive mesenchymal tissue misplacement which is essentially the same thing. Meyerding wrote that these tumors arise from a transition of connective tissue cells in sites where cartilage is not normally found. Bunnell said that these tumors are congenital are found almost always in the hand usually occur singly and represent potential articular cartilages in the phalanges. Haas simply stated that an ecchondroma arises from a site where cartilage does not normally occur. Mason reported that these tumors have never been found in a carpal bone.

Ecchondroma Geschickter (11, 12, 14) stated that the bones and joints begin their development as primitive mesenchymal prechondral connective tissue. This tissue has the ability to develop into bone cartilage synovia perosteum and so forth. It is very undifferentiated tissue. By mucoid degeneration this tissue undergoes modeling then by differentiation cartilage is formed and finally bone. The ends of the tendons which are destined to attach to the ends of the long bones develop and approach their site of insertion into the primitive bone. The precartilage of the end of the tendon and the bony outgrowth from the precartilaginous bone approach each other and unite. If junction occurs normally both are surrounded by perosteum and no abnormality develops. However if there is any malunion or irregularity of union in which the bony outgrowth fails to blend with the end

Fig Enchondromas of the hand

of the tendon and does not become enveloped in periosteum an enchondroma will develop.

In 1930 Dean Lewis said that although the tendon developed from fibrous connective tissue the tendon insertion developed from pre-cartilaginous connective tissue.

Tumors of the tendon sheath. Tumors of the tendon sheaths were first reported by Von Chassagnac in 1852 and have long been considered rarities. The least common of all of these tumors according to Buxton is the chondroma. In 1923 he wrote that the chondroma could occur within the tendon sheath and when such was the case usually was associated with trauma. Some authors have considered that these intrasheath chondromas come from the synovia while according to others they arise from tissue of mesenchymal origin at the edge of the synovia of the joint or sheath.

Geschickter (14) has said that the enchondroma is, by far the most common of the cartilaginous tumors of the tendon sheath.

King stated that chondromas developed from cells of the synovial membrane of the tendon sheaths which cells were capable of forming cartilage when exposed to an adequate stimulus. Hence he felt that the chondroma was the result of metaplasia of the cells of the synovial tendon sheath.

The most accepted hypothesis at this time seems to be that of Niosi and Castiglioni who stated that the primitive reticuloendothelial cell, normally present in the synovial membrane could develop into cartilage by metaplasia in response to an adequate stimulus. This stimulus usually is thought to be multiple rather than single and to consist in repeated slight trauma.

MATERIALS AND METHODS

In this study the operative specimens of tumors of the hand at the Mayo Clinic from 1908 to 1945 were sectioned and studied and all the case histories were reviewed.

Only those tumors from which a pathologic specimen suitable for section was available were included in the series. If a specimen was not available and pathologic study was not possible the case was dropped from the series.

Each case was studied clinically and pathologically. The case was reviewed to determine age, sex, presence of pain, trauma, pathologic fracture, whether the tumor was single or multiple and its location in the hand.

Hyaline cartilage was used as a normal for comparison. Variations from this normal as found in the tumors, were graded in an ascending scale of 1 to 4. The tumors were studied microscopically for vascularity, myxomatous

Fig. 2 a, left, Pathologic fracture b, enchondromas of the hand.

change malignant change cellularity calcification of cartilage and recurrence

Roentgenograms in each case were studied and the diagnosis of the roentgenologist was compared with that of the pathologist

The work was confined to tumors of the hand and the carpal bones of the wrist

Forty two cases of cartilaginous tumor of the hand comprise this series Of the forty two 30 were cases of enchondroma (71.43 per cent) and 12 of echondroma (28.57 per cent) One instance of enchondroma or chondrosarcoma was malignant

CLINICAL FINDINGS

Enchondroma Enchondroma was found in the small bones of the phalanges in 25 cases and in the metacarpal bones in 15 cases. Hence these tumors were more common in the phalanges.

A history of pain was elicited in 26.6 per cent of the 30 cases of enchondroma and always was associated with pathologic fracture (Fig. 2a) Pathologic fracture occurred in the same cases in which a history of pain was noted The remainder of the patients came to the surgeon because of swelling of the finger or metacarpal bone (Fig. 2b) but not because of pain

The ratio of males to females was 17:13 and the average age at the time of operation was 35 years

Of the enchondromas it was found that 5 were multiple and 25 were single tumors

Tumors of the tendon sheath Two cases of tumors of the tendon sheath were found in the 42 cases of the series Both of them were enchondromas One of these tumors was a single enchondroma but the other was more interesting in that there were 5 separate chondromas in the tendon sheath (Fig. 3a)

In both cases a preceding history of trauma was noted Both patients were men and the site in each instance was a flexor tendon sheath

Echondroma The ratio of males to females was 1:1 and the average age was 33.6 years

These tumors occurred with almost equal incidence on the phalanges and metacarpals They arose at the insertion of a tendon usually on the proximal side and caused a lump or protuberance of the bone

It was found that trauma was associated in 4 cases but in each instance after the tumor had arisen After the swelling had developed the patient bumped the enlargement and realized that a tumor was present In the same 4 cases a history of pain associated with the

Fig. Enchondromas of the hand.

of the tendon and does not become enveloped in periosteum an enchondroma will develop.

In 1930 Dean Lewis said that although the tendon developed from fibrous connective tissue the tendon insertion developed from pre-cartilaginous connective tissue.

trauma had been given and the patients in these cases were the only ones in cases of enchondroma that did mention pain. No pathologic fractures were encountered.

In 2 of the cases more than one tumor had developed and in 10 single lesions.

ROENTGENOGRAPHIC OBSERVATIONS

Enchondroma. The roentgenographic picture of these tumors caused the roentgenologist to suspect the presence of chondroma in 50 per cent of the cases (Fig. 2b).

The typical picture was that of the so-called bone cyst which was seen as a small round area of decreased density in the center of the bone. The cortex usually was expanded and thinner than it normally is. The outline was round and regular and appeared in the center of the shaft.

Enchondroma. In contrast the roentgenologist was able to make the diagnosis in almost all of the cases of enchondroma. The lesion in this case appears at the periphery and one end of the bone. The bony elements of the base of the enchondroma show plainly as an elevation of bony structure.

PATHOLOGY

At the Mayo Clinic in a 10 year period from 1935 to 1945 the relationship of enchondroma to enchondroma in all sites and in all bones of the body was 64.13 per cent enchondroma and

35.87 per cent enchondroma. However when the cartilaginous tumors of the hand alone were considered, it was found that the relationship was reversed and that enchondroma occurred in only 28.57 per cent and enchondroma occurred in 71.43 per cent. Hence, the enchondroma occurs much more commonly in the hand and much less commonly in the foot, than in any other location in the body.

Enchondroma. These tumors occur most frequently in patients between the ages of 20 and 30 years.

The vascularity of these tumors was graded from 1 to 4 with normal hyaline cartilage used as a control. An average of 2 plus was found. Thus these tumors have an increased blood supply (Fig. 3b).

The degeneration of an enchondroma is interesting and was investigated thoroughly. The literature varies widely on this subject and lists many different kinds of degeneration, such as fatty hyaline, calcium and fibrous. In this series myxomatous tissue was considered as a degenerative phase of a hyaline enchondroma and was found in 53 per cent of all the enchondromas. This tissue did not occur regularly in just one area of the tumor such as central or peripheral but was located at random and varied from tumor to tumor. The extent of this degeneration was graded from 1 to 4 and an average of 2 was obtained.

No other type of degeneration occurred except in 6 cases in which deposits of calcium were seen. This calcium *not* in the form of bone was usually small in amount and deposition occurred in conjunction with myxomatous degeneration. There was no site of predilection.

Ecchondroma These tumors occur most frequently in patients from 10 to 25 years of age. The tumors are bony outgrowths surmounted by a cartilaginous cap (Figs. 3c and 4).

The microscopic picture of an ecchondroma is varied in accordance with the site of section. If the section is taken across the bony base it will apparently be composed entirely of bone and if the section is taken high on the cartilaginous cap the tumor will appear to be composed entirely of hyaline cartilage (Fig. 3c).

The blood supply of an exostosis osteochondroma or enchondroma comes from the bone marrow both the bony element and the cartilage being supplied from this same source. Evidence of abnormally increased blood supply to the ecchondroma was not found.

Degeneration was observed rarely and when evidence of it was found it was very slight and took the form of a mild myxomatous change in the cartilage elements. The cartilage itself was not divided into many lobes or lobules as it is in an enchondroma and the tumor did not grow from many sites or sources as does an enchondroma.

Malignancy Malignant cartilaginous tumors may arise from either an ecchondroma or an enchondroma. According to the reported cases in the literature it is more common for them to arise from an enchondroma than from an ecchondroma.

It always has been stated that a chondroma will recur if some enchondroma cells are misplaced, allowed to transplant or left *in situ*. This is not true of ecchondroma. The fact that a chondroma recurs after one removal does not necessarily mean that it is malignant, although malignancy is difficult to determine in these cases. The criteria for malignancy in an enchondroma are increased cellularity and the presence of an occasional mitotic figure. Mitotic figures may be difficult to find in what would otherwise be a benign enchondroma.

Fig. 4. Gross appearance of an ecchondroma.

In the entire series 5 tumors recurred. One recurrence was that of an ecchondroma and was due to slow growth of remnants of the cartilage cap. The other 4 recurrences were of enchondromas, only 1 of which was considered malignant. Evidence of metastasis was not found.

The 1 malignant tumor was a chondromyxosarcoma (incidence 2.62 per cent in our series). The patient was operated on 5 times at 2 year intervals for a recurring benign chondroma and it was not until the fifth operation that a diagnosis of low-grade malignancy could be made.

TREATMENT

In all cases of enchondroma treatment was conservative. The tumor tissue was curetted leaving as much of the bony shell as possible. Bone grafts were used where needed. Also in cases of ecchondroma treatment was conservative and consisted of removal of the protuberance and as much of the bony base as was necessary to restore the normal continuity of the bone.

COMMENT

The cartilaginous tumors as a group have been called osteochondromas and this has created some misunderstanding. An ecchondroma can also be called an exostosis or an osteochondroma and is found near the ends of both the long and the short long bones at or near the site of a tendon insertion. An enchondroma can also be called a chondroma and occurs most commonly in the short bones of the hands and the feet although it can also

occur in any bone which has had an embryonic cartilaginous origin. The membrane bones of the face and skull are not the sites of chondromas. The chondroma occurs centrally in bone and grows from several centers expanding the cortex. It is silent until it reaches a size large enough to be recognized as a swelling or tumor of the hand. It often calls attention to itself by a pathologic fracture. The roentgenologist commonly makes a diagnosis of simple central bone cyst.

The enchondroma or osteochondroma arises from the cortex of the bone and has a bony base and a cartilaginous cap.

Enchondroma. The ideas concerning origin of these tumors are many and varied. The one which has best withstood the test of time is that of primitive cartilage rests. It has been noted that chondromas occur with the greatest frequency in regions where there are a great many small joints and bones. It is known that bone which is not membranous is first preceded by primitive connective tissue or mesenchyma. This connective tissue differentiates into areas or strands from which bone is formed by differentiation. Also from this same tissue and from primitive cell tissue comes the synovia of the joint and the insertion of the end of tendons and the marrow and cortex of the bone. The bone itself is formed first by differentiation into primitive cartilage and then replacement by the osteoclasts and osteoblasts to form the actual bone.

The synovia of joints and the cartilaginous bony ends which articulate each with the other are also formed from this same tissue. The articular cavities are formed by degeneration of this primitive connective tissue and its subsequent absorption.

Thus it is thought that at the time of replacement of the primitive cartilage in order to form bone or at the time of the absorption of the primitive connective tissue in order that the actual joints and joint spaces may result, some of this early mesenchymal cartilaginous tissue is caught or left behind and occurs as a rest in the end-result the adult bone. These rests still retain their primitive quality and are able to form cartilage although they do not lie where cartilage normally should be. Therefore it is thought perhaps in response to

trauma (occurs in 60 per cent of cases) or some other stimulus that these cells begin to differentiate and grow in the adult bone and a central chondroma results in a site where cartilage should not be.

According to some authors the myxomatous degeneration of an enchondroma is further evidence of differentiation and that it would be followed by the formation of bone so that an echondroma would result. This did not seem to be the case in this series as no early bone was found in a true enchondroma regardless of the amount of the myxomatous change. Hence except for the fact that the echondroma and the enchondroma basically came from the same primitive connective tissue cells for their formation as also does adult bone cartilage and other mesenchymal structures, they cannot be said to be associated one with the other in development. One does not develop from the other nor is one a stage in the formation of the other.

Echondroma. The echondroma occurs near the ends of the long bones and the ends of the short long bones. It does not often occur in the membrane bones of the face and skull. It does not occur in the hand with greater frequency than in any other location in the body.

Many different hypotheses of origin have been formulated but the basic one of Geschickter (9-11) seems the most plausible. He stated that the primitive mesenchymal connective tissue first forms a tissue layer which differentiates into cartilage which is then replaced by bone. The end of the tendon is also composed of this primitive connective tissue which likewise has the ability to differentiate into cartilage or bone. The epiphyseal end of the bone puts out a protuberance which is destined to unite with the primitive connective tissue of the end of the tendon. If this union is effected smoothly and the junction is adequate it is covered with periosteum from the bony cortex and no tumor results. However if this junction of the tendon and bone is not good and is irregular or misplaced the periosteum from the cortex of the bone covers only the bony protuberance which was to be the site of insertion of the tendon and does not blend and cover the precartilaginous end of the tendon. The cells of this misplaced precarti-

lagnous end of the tendon are still undifferentiated connective tissue cells and when they begin growth in response to some stimulus or perhaps no stimulus an enchondroma or osteochondroma results. This is an attempt on the part of these cells to form bone and takes the form of an articular end of bone. As a result the enchondroma has a bony base which at the apex blends with primitive cartilage. The bony base is surmounted by the cartilaginous cap which in the outer layers is adult hyaline cartilage.

Therefore the enchondroma is found at the ends of the long bones and the short long bones usually on the proximal side of the insertion of a tendon and not on the bones of the skull and the face, such bones being membranous in origin. The enchondroma is always peripheral (the perichondroma of Virchow) and never central. No correlation of enchondroma with such diseases as syphilis, tuberculosis or rickets was found in this series.

Tumors of the tendon sheath. Concerning the origin it seems reasonable that an enchondroma could occur in a tendon sheath at the site of insertion of the tendon and arise from the primitive mesenchymal cells of connective tissue. It also seems reasonable that an enchondroma could occur in the tendon sheath far from the insertion of the tendon. In 2 cases in the literature this occurred. In such cases it is thought that the cartilage cells arise from those of primitive synovial membrane in response to an adequate stimulus.

The total number of reported cases of tumors of the cartilaginous tendon sheath still remains small and variable. One author (22) stated 12 as the number in the literature and another 40 (17-19). Hence it is difficult to say which occurs more commonly, the enchondroma or the perichondroma. The exact nature of origin of these tumors is in doubt, probably because of the small number of cases on record. It is probable that these tumors, both enchondroma and perichondroma, arise from a primitive mesenchymal connective tissue cell which is associated with the synovia of the tendon sheath and the joint, and that they are capable of differentiating into either cartilage or cartilaginous bone in response to an adequate stimulus.

SUMMARY AND CONCLUSIONS

Cartilaginous tumors of the hand on the basis of pathology may be divided into two types: enchondroma and perichondroma. The synonym for enchondroma is chondroma. Perichondroma is called perichondroma, osteochondroma, and exostosis. (The word osteochondroma is restricted to the enchondroma.)

The fact that the entire group of cartilaginous tumors is commonly called osteochondroma has led both in the past and in the present to a great deal of confusion. It is better to use the terms enchondroma and perichondroma.

Distinction between the two cannot be made with slide and microscope alone.

An enchondroma is usually a small cartilaginous tumor located centrally in the bone shaft, growing from many centers and expanding in all directions. Rate of incidence of pathologic fracture in our series was 26.6 per cent. The enchondroma occurs much more often in the hand than does the perichondroma (3:1). These tumors, in comparison to normal hyaline cartilage, show increased vascularity, calcium deposition, and myxomatous degeneration.

Two tumors of the tendon sheaths were found, both of which were perichondromas. In one of these cases multiple perichondromas of the sheath had developed, and this is good evidence that an enchondroma can occur in the tendon sheath away from the site of tendon insertion.

The perichondromas occur peripherally in bone near the end of the shaft and have a bony base and cartilaginous cap.

Either type of tumor may be malignant, in which case it is usually a sarcoma. In this series 2 per cent were malignant. Both types are prone to recur, although recurrence does not mean malignancy, unless a mitotic figure can be found.

The treatment in both types is conservative operation.

STUDIES ON VAGOTOMY IN THE TREATMENT OF PEPTIC ULCER

I The Use of Insulin in Testing for Completeness of Vagotomy

I F STEIN JR M.S. M.D. and KARL A. MEYER, M.D., F.A.C.S., Chicago, Illinois

THE relationship of the vagus nerves to normal and pathologic gastric physiology has been studied for many years. The cephalic phase of gastric secretion mediated entirely by the vagi was first demonstrated by Pavlov in 1890 (1, 2) and later confirmed by Ivy (3) and Farrell (4). The copious work in this field has been summarized by review articles (5, 14).

In 1912 vagotomy was first advocated in man as treatment for gastric crises in tabes by Exner and Schwarzmänn (15). In 1915 Exner and Schwarzmänn reviewed the literature and presented 14 cases of subdiaphragmatic vagotomy (16). In patients a simultaneous gastroenterostomy was performed for pylorospasm, decreased gastric peristalsis and atonia. The variability of the anatomy of the vagus nerves was discussed.

Vagotomy as a treatment for peptic ulcer was advocated by Stierlin (17) in 1920. Latarjet (18), Bricher (19) and Schiassi (20) in 1925 and has since been investigated in both experimental animals and man by many others (8, 10, 11, 14, 21, 34). It has often been demonstrated experimentally that incomplete vagus section produces no significant change in gastric activity (8, 12, 29, 36). Weinstein's 2 attempts at complete vagotomy reported in 1944 (37) were unsuccessful and led him to conclude that complete vagotomy in man is difficult to achieve. Prior to 1943 there are no reports of patients having definite complete vagotomy. Dragstedt's first report of total vagotomy in 1943 (38) and other papers which followed (39-53, 102) have caused renewed interest in the problem. It is

clear from both the long clinical experience with partial vagotomy and the experimental evidence that incomplete vagotomy is of little if any value in the treatment of peptic ulcer. It is therefore of great importance in the evaluation of vagotomy to have a method for testing vagus function following attempted complete vagus section. Two such methods are available: sham feeding (36, 41) and the use of insulin. This paper is concerned primarily with the insulin test of vagus action on the stomach.

The effect of insulin hypoglycemia on the stomach has been thoroughly studied. The increase in gastric motility following insulin hypoglycemia was first demonstrated by Bulato and Carlson (54) in 1924 and has since been investigated by many others (55, 69). The effect of insulin on gastric secretion was originally thought to be inhibitory by Collazo (70) but no inhibitory effect was noted by Ivy (71) and Wrendensky (72). The stimulating effect of insulin hypoglycemia on gastric acidity was first noted by Detre and Silvo (73) in 1925 and later confirmed by others (74-89). The mechanism of action was considered a central vagal effect by Quigley (58), Okada (81), Boldyreff (85), Mulinos (66) and Bahkin (12). The abolition of this stimulatory effect by vagotomy was described by Okada (81), LaBarre (83), Bahkin (12) and Jemerin (36). Thus insulin provokes increased gastric motility and secretion by hypoglycemic stimulation of the vagal center and this action is abolished by complete vagotomy.

METHOD

The basic method which we have employed was first described in man by Simici in 1927 who reported the effect of 15 units of insulin intravenously on both the motility and secretion of the stomach in 20 normal subjects (57).

STUDIES ON VAGOTOMY IN THE TREATMENT OF PEPTIC ULCER

I The Use of Insulin in Testing for Completeness of Vagotomy

I F STEIN JR. M.S. M.D., and KARL A. MEYER, M.D. F.A.C.S., Chicago, Illinois

THE relationship of the vagus nerves to normal and pathologic gastric physiology has been studied for many years. The cephalic phase of gastric secretion mediated entirely by the vagi was first demonstrated by Pavlov in 1890 (1, 2) and later confirmed by Ivy (3) and Farrell (4). The copious work in this field has been summarized by review articles (5, 14).

In 1912 vagotomy was first advocated in man as treatment for gastric crises in tabes by Exner and Schwarzmunn (15). In 1915 Exner and Schwarzmunn reviewed the literature and presented 14 cases of subdiaphragmatic vagotomy (16). In 9 patients a simultaneous gastroenterostomy was performed for pylorospasm, decreased gastric peristalsis and atonia. The variability of the anatomy of the vagus nerves was discussed.

Vagotomy as a treatment for peptic ulcer was advocated by Stierlin (17) in 1920. Later, Jet (18), Brucher (19) and Schiassi (20) in 1925, and has since been investigated in both experimental animals and man by many others (8, 10, 11, 14, 21, 34). It has often been demonstrated experimentally that incomplete vagus section produces no significant change in gastric activity (8, 12, 29, 36). Weinstein's 2 attempts at complete vagotomy reported in 1944 (37) were unsuccessful and led him to conclude that complete vagotomy in man is difficult to achieve. Prior to 1943 there are no reports of patients having definite complete vagotomy. Dragstedt's first report of total vagotomy in 1943 (38) and other papers which followed (39-53, 102) have caused renewed interest in the problem. It is

clear from both the long clinical experience with partial vagotomy and the experimental evidence that incomplete vagotomy is of little if any value in the treatment of peptic ulcer. It is therefore of great importance in the evaluation of vagotomy to have a method for testing vagus function following attempted complete vagus section. Two such methods are available: sham feeding (36, 41) and the use of insulin. This paper is concerned primarily with the insulin test of vagus action on the stomach.

The effect of insulin hypoglycemia on the stomach has been thoroughly studied. The increase in gastric motility following insulin hypoglycemia was first demonstrated by Bulato and Carlson (54) in 1924 and has since been investigated by many others (55, 69). The effect of insulin on gastric secretion was originally thought to be inhibitory by Col-lazo (70) but no inhibitory effect was noted by Ivy (71) and Wwendensky (72). The stimulating effect of insulin hypoglycemia on gastric acidity was first noted by Detre and Sivo (73) in 1925 and later confirmed by others (74, 89). The mechanism of action was considered a central vagal effect by Quigley (58), Okada (81), Boldyreff (85), Mulnos (66) and Babkin (12). The abolition of this stimulatory effect by vagotomy was described by Okada (81), LaBarre (83), Babkin (12) and Jemerin (36). Thus insulin provokes increased gastric motility and secretion by hypoglycemic stimulation of the vagal center and this action is abolished by complete vagotomy.

METHOD

The basic method which we have employed was first described in man by Simici in 1927 who reported the effect of 15 units of insulin intravenously on both the motility and secretion of the stomach in 20 normal subjects (57).

From the Hektoen Institute for Medical Research of the Cook County Hospital and from the Departments of Surgery of the Cook County Hospital and Northwestern University Medical School, Chicago.

Dr. Stein is Abbott Fellow in Surgery, Northwestern University Medical School.

76) Jemerin (36) Dragstedt (41) Thornton (44) and Hollander (89) have used the acid response to insulin hypoglycemia as test for completeness of vagotomy

Our procedure was as follows. The subject was given a standard soft diet at 4:30 p.m. and nothing by mouth thereafter. A Levine tube was passed through the nose into the stomach at 7:30 p.m. and the stomach emptied. Continuous intragastric suction was maintained from 8 p.m. until 8 a.m. for a determination of the night secretion. The determination of night secretion is not an integral part of the insulin test but preceded the test in the majority of our cases. At 8 a.m. a second tube with a rubber balloon attached was passed into the stomach. The balloon capacity was about 200 cubic centimeters but in order to avoid mechanical stimulation only 10 to 50 cubic centimeters of air were used in the balloon during the test. The balloon was placed in the cardia of the stomach and its position confirmed by inflation and gentle withdrawal of the attached tube until there was a slight tug as the balloon reached the cardiac sphincter of the stomach. By this means it was assured that the balloon was not in the pylorus where it might cause mechanical stimulation. The balloon was then only partially inflated and connected to a water manometer. Continuous recordings were made on a slowly moving kymograph.

A control period of basal secretion and motility was then observed for at least 1 hour. The stomach was aspirated continuously and a specimen collected at 15 minute intervals for acid determination. If the acidity of the stomach showed marked spontaneous decrease or increase the basal period was extended until a fairly constant level was reached. Then 14 to 16 units of regular insulin were injected intravenously and the effect on motility and acidity was noted for $1\frac{1}{2}$ to 2 hours. Blood sugar determinations were not made during the preoperative tests but in each instance a determination was made at the height of the hypoglycemia during the postoperative tests as a control. If moderate hypoglycemic symptoms did not occur the injection of 15 units of regular insulin intravenously was repeated at the end of $1\frac{1}{2}$ hours.

If the blood sugar did not fall to or below 55 milligrams per cent during the postoperative test the test was repeated.

RESULTS

Twenty-seven patients with peptic ulcer have been tested before and after vagotomy by the method described. An average of 10 hours of motility tracings was made on each patient. An additional 3 patients had only acid determinations as described making a total of 30 patients.

Acid response. An average preoperative curve of 22 comparable patients with duodenal ulcer is shown in Figure 1. (The acid response in patients having had previous gastric resection was inconstant and is not included in the composite curve.) There was usually an early decrease in the free acid level following the insulin injection. This fact is obscured in the composite curve (Fig. 1) for although the majority had maximal decrease at 30 minutes following insulin 3 patients had a marked increase in free acid at 30 minutes with maximum depression at 15 minutes. The increase in free acid was usually noted between 45 minutes and 1 hour starting at the height of the hypoglycemic reaction. In 3 instances there was no hypoglycemic reaction nor acid response. The test was repeated after $1\frac{1}{4}$ hours with the usual reaction. One patient had a severe insulin reaction requiring intravenous glucose and in this instance only the inhibitory phase was noted. The test was repeated the following day with the usual reaction. Thus it was possible to elicit a definite positive response in all cases preoperatively although in some instances the test had to be repeated before a positive response occurred.

Ten days to 2 weeks after operation 18 of the 22 patients showed no acid response to insulin hypoglycemia. These are considered to have had complete vagotomy. In 12 the free acid was zero during both the basal period and following insulin hypoglycemia. In 3 cases there was a higher basal level than in the above group and following hypoglycemia a marked acid response was observed. These are considered to be cases of incomplete vagotomy. On 3 occasions 1 of the 22 pa-

Fig. 2 The effect of insulin on gastric acidity before and after vagotomy

tients whose postoperative curve is not shown on Figure 1 showed a doubtful reaction being midway between the group listed as complete and incomplete.

For analysis of results the response to insulin hypoglycemia may be considered the maximum response to insulin in a 15 minute period minus the maximum secretion in a 15 minute period of basal secretion.

The preoperative response to insulin in 22 patients averaged 53 clinical units of free acidity with a range of 17 to 95 clinical units (The average was 3.7 milliequivalents of hydrochloric acid per 15 minutes with a range of 8 to 6.9 milliequivalents).

The postoperative response to insulin in the 18 patients considered to have complete vagus section was zero.

The postoperative response to insulin in the 3 patients considered to have incomplete vagus section averaged 40 clinical units of free acidity with a range of 34 to 47 clinical units. (The average was 5.1 milliequivalents per 15 minutes with a range of 4.6 to 5.5 milliequivalents.)

The patient in whom completeness of the vagotomy was considered doubtful had a high basal secretion level. The response which followed insulin hypoglycemia was equal to but did not exceed the control basal level.

Motor response. All 27 patients before surgery showed spontaneous type I and occasionally type II or III hunger contractions (Fig. 2). If the insulin was given during a period of gastric activity there was an immediate suppression of hunger contractions. This lasted from $\frac{1}{2}$ to $1\frac{1}{2}$ hours and was followed by a period of hypermotility in the majority of cases. In a few instances the motility pattern following insulin was similar to the control period and did not show hypermotility. There was no constant correlation between the onset of hypoglycemia and that of the hypermotility nor was the onset of the secretory response correlated in any constant manner with the motor response. After surgery 24 of 27 patients tested showed no hunger contractions during either the control period or following insulin hypoglycemia (Fig. 3). The motility tracings showed tonus rhythm but no type I, II, or III hunger contractions. An increase of the fasting period to 22 hours before the insulin test in 7 cases had no effect on the motility. These patients all had a negative acid response following hypoglycemia.

Two of the 3 patients classed above as having had incomplete vagotomy on the basis of the acid response showed spontaneous type I or II hunger contractions postoperatively during the basal control period after 16 hours.

Fig 2. Preoperative insulin test—motility tracing showing spontaneous and insulin induced hunger contractions.

of fasting. The third patient had type I hunger contractions following insulin hypoglycemia.

The patient in whom completeness of the vagotomy was classified as doubtful did not demonstrate definite hunger contractions after operation.

Eight patients who were considered to have complete vagus section were tested 3 to 9 months following vagotomy. The results were similar to the early postoperative tests with 1 exception. This patient had had a transabdominal vagotomy and posterior gastroenterostomy 9 months previously for duodenal ulcer with negative response to the insulin test 11 days postoperatively. Mild ulcer symptoms had returned 3 weeks before testing. Insulin test showed a positive acid response and both spontaneous and insulin induced type I and II hunger contractions.

In summary of the 30 patients tested in 5 vagus section was incomplete in 2 completeness

was doubtful and in 1 vagal function had recurred after a period of 9 months i.e. in 8 patients vagotomy was incomplete or completeness was doubtful. Four of these 8 patients have had recurrence of ulcer symptoms.

DISCUSSION

For many years the action of insulin on acidity and motility of the stomach was controversial. This controversy is explained by the biphasic action of insulin on the stomach (57, 62, 65, 66, 68, 69, 76, 82, 87).

This action has been noted in the preoperative studies, i.e. an initial decrease in acidity and motility is followed by marked increase in the acid and usually motility.

It has been frequently demonstrated that following complete vagotomy in experimental animals hunger contractions are present although they may be diminished (90-97).

Decreased gastric motility with normal or decreased hunger contractions have been

Fig. 3. Postoperative insulin test—motility tracing showing no spontaneous or insulin induced hunger contractions following complete vagotomy

noted in man after vagotomy (43 44 49 52). Our findings indicate that after complete vagotomy there is an absence of hunger contractions in the fundus of the stomach. This difference in findings may be due either to the location of the balloon in the stomach or to mechanical stimulation of motility by distention of the balloon. In order to avoid mechanical stimulation in our tests the balloon was only partially filled using 10 to 50 cubic centimeters of air. The absence of spontaneous or insulin induced hunger contractions in the fundus of the stomach in man following complete vagotomy as compared to experimental animals may be explained on the basis of a difference in vagal function in the two species. It is possible that this may also be related to the fact that man is subject to peptic ulceration a condition rarely seen spontaneously in experimental animals.

Gastric motility and acidity are subject to marked spontaneous variations. It is there-

fore essential to know the status of the gastric activity before a test of gastric function is started. The period of at least 1 hour before insulin is given serves as a control and is designated basal secretion (98-101) and motility. After vagotomy a small amount of spontaneous acid secretion during the basal period will tend to nullify the significance of a similar amount following insulin hypoglycemia.

INTERPRETATION OF POSTOPERATIVE RESULTS

The presence of acid response to insulin hypoglycemia and of spontaneous or insulin induced hunger contractions in the fundus of the stomach is positive evidence of incomplete vagotomy. The acid response to insulin hypoglycemia in cases of marginal ulcer following gastric resection may be unreliable due to the previous removal of acid producing mucosa. Motility studies in these cases before and after vagotomy in which both spontaneous fasting motility and that induced by in-

ulin hypoglycemia are observed are particularly useful as an indication of complete or incomplete vagus section. Such studies have been made in 5 patients, 1 of whom showed spontaneous type I II and III hunger contractions following vagotomy indicating in complete vagus section. In this case the hunger contractions were abolished by a second vagotomy to indicate complete vagus section.

The absence of acid response to insulin hypoglycemia and of spontaneous or insulin induced hunger contractions may be indicative of complete vagotomy. However the following factors must be considered. There must be a sufficient degree of hypoglycemia to produce central stimulation of the vagus. The hypoglycemia must not be too profound or there may be no vagal stimulation.

We have no positive evidence that a physiologically complete vagotomy as shown by a negative insulin test corresponds exactly to a complete anatomical vagotomy. The patient who tested complete after vagotomy and incomplete 9 months later may have had regeneration of the nerves. However a very small percentage of fibers may have remained which did not show function when first tested but which have assumed the functional innervation of the entire stomach.

Anatomical studies have been made in 2 cases. One patient died on the 8th postoperative day of cardiac failure uremia and lower nephron nephrosis following a blood transfusion reaction. Careful dissection of the vagi showed grossly an approximate 99 per cent vagotomy. There were 2 nerve fibrils which branched from the left vagus into the esophagus. It could not be ascertained with certainty if these small nerves reached the stomach. No insulin test was done on this patient.

A second patient died of bronchopneumonia (unassociated with the vagotomy) 3 months after surgery. The postoperative insulin test was negative. Grossly there appeared to be nerve fibers connecting the cut ends of the main nerve trunks (identified by silver clips placed at surgery).

SUMMARY

Incomplete vagus section has little effect on gastric physiology and is of no permanent

value in the treatment of peptic ulcer. In order to evaluate vagotomy it is essential to determine whether complete vagus section has been accomplished. Insulin provokes increased gastric motility and acidity by hypoglycemic stimulation of the vagal center. This action is abolished by complete vagotomy. The literature has been reviewed and a method for testing vagal continuity described. Criteria for the interpretation of the insulin test are discussed.

THE RÔLE OF TRANSVAGINAL ROENTGENTHERAPY IN THE TREATMENT OF CARCINOMA OF THE CERVIX

J. A. DEL REGATO M.D. Columbia, Missouri

TRANSVAGINAL roentgentherapy has acquired a definite position in the treatment of carcinoma of the cervix judiciously employed. It is a valuable adjunct of the external pelvic irradiation and is capable of replacing with certain advantages the classic methods of intracavitary curietherapy.

Transvaginal irradiation with roentgen rays was tried by many of the pioneers of radiotherapy before radium became widely available. Caldwell and Pennington designed special tubes for the purposes of this and other transvaginal irradiations. Allen pointed at the usefulness of this approach but recognized the necessity of adjunctive external irradiation in most cases of carcinoma of the cervix. Pusey, Duncan, and others observed and reported favorable results. Stuver described vividly the elaborate procedures of one of these early trials. Tousey recommended the usefulness of the Ferguson speculum.

The inadequacy of equipment and dosimetry as well as a lack of understanding of radiophysiology of tumors often led these early attempts to failure and disillusionment and publications on the subject ceased almost abruptly. With a few exceptions (Dachtler) continued trials of transvaginal irradiation of carcinoma of the cervix passed unpublished (Chance treated successfully several patients one of which is reported living 40 years after treatment). With the development of techniques of curietherapy and progressive improvement of results transvaginal roentgentherapy was almost entirely forgotten.

In 1921 Merritt made an attempt to revive this form of treatment but rapidly abandoned it because of the hazards associated with high tension leads and unprotected tubes. With the advent of shockproof equipment Merritt from 1937 on became the forceful advocate of trans-

vaginal roentgentherapy. Abroad, Martius seems to have been the only persistent supporter of this form of adjunctive treatment.

THE PURPOSE

In the majority of cases of carcinoma of the cervix a thorough external irradiation is the most important single factor leading to permanent control. But the external irradiation is seldom sufficient to the task of sterilizing the tumor. The diminution of secondary infection and inflammation and the diminished dimensions of the tumor area, resulting from the external pelvic irradiation make it possible for the internal phase of the treatment to achieve the destruction of the remnant of the tumor. The internal treatment compensates for the insufficient total dose and rather weak daily dose received by the remaining carcinomatous cells. A skillful application of radium, in the uterus and in the vagina, succeeds in controlling the residual tumor in an appreciable number of cases. We have no quarrel with this classic form of treatment that could yet yield better results. The question before us is whether transvaginal roentgentherapy can achieve the same purposes with less disadvantages and whether or not it can improve upon the results of curietherapy of carcinoma of the cervix.

Transvaginal roentgentherapy has been used to substitute the vaginal application of radium only while retaining the intrauterine application (Martius Taylor). This procedure has unquestionable merits since it is the vaginal application of radium that is most often inadequate for several reasons. We have preferred to substitute entirely the vaginal and uterine radium applications in order better to evaluate the merits of transvaginal roentgentherapy.

Transvaginal roentgentherapy may result in a relatively more homogeneous distribution of radiations throughout the cervix and adjacent

structure than is obtained with the use of radium. Consequently the sterilization of carcinoma that is limited to this area can be accomplished with a lesser volume of dose. This fact results in a widening of the margin of safety between the necessary destruction of the tumor and the untoward injury to normal structure. In the treatment of carcinoma arising on a cervical stump the impossibility of introduction of an intracervical radium applicator hampers the choice of a successful radiotherapy transvaginal roentgentherapy is the treatment of choice in this case.

Following external irradiation the irradiation of a single well circumscribed field to the cervix and uterus, and permitting the irradiation of adjacent portions of the parametria is most satisfactory. In contrast, the method permits the daily external irradiation of the potentially malignant area. It is true that with the use of a single field it is possible that could be expected to be effective external rays partially into the parametria but when transvaginal roentgentherapy has been considered external irradiation with attractive and costless tubes may extend to a large pelvic wall.

Wasson and Felson have a very satisfactory technique of transvaginal roentgentherapy in carcinoma in the irradiation of the cervix through four adjacent circular fields in a central overlapping fashion. This seems not to allow irradiation field junctions in an attempt to irradiate more intensively the parametrial region, but it may be observed that it is based upon an experimental study of the physical distribution of radiation. Felson (1947) advocates the use of four adjacent rectangular (2.4 by 3.0 cm.) for the irradiation of the cervix and uterus.

Nolan and Stanbro have made a very commendable physical study of the distribution of radiation throughout the pelvic transvaginal roentgentherapy but this study did not take into account the combined effectiveness of the external and internal irradiation. Although they do not draw this conclusion, Nolan and Stanbro's work may suggest to others that the use of multiple small circular fields is preferable since it may extend further out the theoretically effective dose. This apparent advantage loses its weight when one considers

Fig. 1. Diagram illustrating the technique of transvaginal roentgentherapy in carcinoma of the cervix.

that the plane of lateral extension of a tumor cannot be estimated with any degree of acceptable precision. Since human anatomy and tumor spread are variable. The treatment of a wide neoplastic zone by means of blindly directed narrow beams of radiation can seldom be expected to achieve the all inclusive irradiation that is required for the sterilization of the tumor. A revision of this opinion will be justified however if the results obtained by Wasson and Felson prove the superiority of their mature judgment and method.

THE APPARATUS

Schaefer and Witte designed a roentgen ray tube that can be introduced into the vagina to accomplish an intensive irradiation of the cervix. An improved version reported by Martin and Witte deserves further trial. These tubes however generate a beam of low qual-

ity resulting in poor distribution of radiations throughout the tumor. The same is true of the better known contact therapy units.

Transvaginal roentgentherapy can be carried out satisfactorily with standard roentgen ray unit. In the past units of 200 kilovolts have been preferably used for this purpose (Merritt, Wasson) since they offer the unquestionable advantage of a beam of better quality and a greater homogeneity of distribution of radiations in the potentially diseased area than is obtained with lower voltages. Yet the work with 200 kilovolt units imposes a long target-cervix distance and results in greater penetration than is desirable with consequent over irradiation of the bowel. It is for these reasons that we decided to experiment with lower voltages which permit a shorter distance and a greater dispersion of the beam of rays.

We hold the opinion that the internal treatment in carcinoma of the cervix is nothing but a complement of the external irradiation in the majority of cases consequently we feel that transvaginal roentgentherapy should attempt only to counteract the deficiencies of the external irradiation (in total and daily dose) in the center of the tumor area. This step can be accomplished with moderately penetrating radiations. All patients reported in this paper were treated with a 110 kilovolt unit at 25 centimeter target-cervix distance at present we are treating our patients with a 140 kilovolt unit and with 0.5 millimeter copper filtration.

THE SPECULA

As a means of facilitating the passage of radiations through the vagina Merritt recom-

mended the introduction of a rubber balloon that when inflated kept the vaginal walls from collapsing. He also utilized glass tubes (made out of urine specimen bottles) but finally adopted the more convenient Ferguson hard rubber or bakelite specula.

Erskine made an ingenious contribution with the introduction of a metal speculum with expanding blades. This speculum is useful in the treatment of early lesions but it falls in its purpose if applied in the treatment of advanced ones for it may provoke bleeding and pain. When transvaginal roentgentherapy has been preceded by external irradiation the

cicatricial shrinkage and the mucosal tenderness forbid any attempt of expansion of the vaginal walls.

Wasson has preferred the use of an all metal tube permitting the irradiation of a small circular area. His vaginal tube is very similar to a rectoscope and allows for the insufflation of the vagina for better visualization and aiming of the beam.

During my association with Merritt for the purposes of this study I designed a speculum that avoids the irradiation of the introitus while permitting the expansion of the beam of rays through a shaft transparent to radiations (Figs. 2 and 3). In its present form the use of this speculum results in the irradiation of a circular field that opens to 6 centimeters in diameter at the level of the cervix the pro-

tection of the rectum or bladder is facilitated by removable metal aprons placed within the shaft of the speculum (Fig. 4). The specula are shaped to fit tightly in a special tube head piece that keeps the speculum in place during the irradiation (Figs. 5, 6, 7 and 8). For the requirements of our work we use a set of three specula with different diameters (3.6, 3.8 and 4 cm.) and removable shafts of three different lengths for each of these specula.

THE TECHNIQUE

Following a course of external pelvic roentgenotherapy lasting approximately 6 weeks our patients receive their course of transvaginal irradiations without interval of rest. During this period the moist radioepidermitis of the skin which has resulted from the external

tated a permanent colostomy she remains free of cancer

Bowel complications following radiotherapy of carcinoma of the cervix are neither constant nor fatal, provided that adequate medical or surgical attention is given in time. While an attempt should be made to avoid excessive irradiation through adequate evaluation of doses administered the adoption of a technique of treatment that will with certainty avoid these intestinal complications will result in too marked a reduction of the proportion of cases that are controlled.

Two patients developed an episode of hematuria and pollakiuria approximately 18 months following treatments. In both instances the symptoms subsided without complication. No other urinary complications have been noted after treatment.

Although 12 of the treated patients presented invasion of the bladder or rectum, only in 1 case did a rectovaginal fistula develop during the course of external irradiation. There have been no other fistulas. Three patients who presented evidence of bladder invasion as demonstrated by cystoscopy (and in 1 case by biopsy) are at present free of disease and without development of vesicovaginal fistula. The more homogenous distribution of radiations that results from transvaginal roentgentherapy and the slow and uniform atresia of the upper vagina that invariably follows are probably responsible for the low incidence of fistulas—another desirable feature of transvaginal roentgentherapy.

THE RESULTS

The only available statistic of 5 year results after transvaginal irradiation is the recently reported one by Merritt and Caulk who obtained 95 survivals (32 per cent) in a series of 294 patients in all stages that were treated in this series; however included numerous instances of association with radium therapy. Of 23 cases of carcinoma of the cervix stage II that were treated with external irradiation intracavitary curietherapy plus transvaginal roentgentherapy 12 patients (52 per cent) survived 5 years.

From February 1943 to June 1944 76 patients with carcinoma of the cervix, not pre-

*For the circumstances not permitting an assurance to the contrary.

viously treated, applied for admission to The Ellis Fischel State Cancer Hospital, no patient was rejected and all but 2 with advanced disease received a complete external irradiation followed by transvaginal roentgentherapy. Radium was not used in any case.

Four of these patients died of intercurrent disease and without signs of recurrence before 3 years had lapsed following treatment. Three other patients are at present living with apparent recurrences or metastases. Thirty-five patients have died of cancer or in circumstances that do not permit the assurance that cancer was not the cause of death. A report of the absolute number of local recurrences is not possible since the majority of these patients were not seen by us in the terminal stages, but the majority of them died without vaginal ulceration, bleeding or discharge. Twelve of these patients presented evidence of distant metastases. It is our clinical impression that most of them succumbed to the development of parametrial or extrapelvic recurrences or metastases without local recurrence. The average survival of these 35 patients was 14 months, but the survival was longer the earlier the stage of the disease (Table I). The length of survival of these patients and the elimination of infected bleeding ulcerations justifies the undertaking of treatment of all patients that apply.

In 2 patients treated for a stage III carcinoma of the cervix a postmortem examination revealed no evidence of carcinoma in the pelvis in spite of a very zealous search (several

CONTRIBUTIONS OF ANIMAL EXPERIMENTATION TO THE TREATMENT OF SURGICAL SHOCK

DALLAS B. PHEMISTER, M.D. F.A.C.S. Chicago, Illinois

NEXT to anesthesia and antiseptics perhaps no other single factor has contributed more to the advancement of modern surgical therapy than the introduction of efficient methods of prevention and treatment of shock. In this development the contributions of animal experimentation have been of very great importance.

When it became possible with anesthesia and antiseptics to operate painlessly and obtain wound healing with a low incidence of infection all fields of the body were gradually invaded by the surgeons and operations of greater magnitude were introduced. This increased the frequency and amount of blood loss and correspondingly the frequency and severity of circulatory disturbance accompanying operations. Also as surgery was extended to structures within or bordering on the abdominal cavity increased difficulty was encountered postoperatively in the administration of water and food by mouth and there was greater loss of fluid from vomiting than before. Both accidental surgical and war wounds posed similar problems of loss of blood and body fluid and of inadequate fluid intake.

During the first decade of the antiseptic era and in most quarters for many years there after the causation of surgical shock was inadequately appreciated. This was because the medical profession was so deeply imbued with the age old idea that shock was a state of marked depression brought on principally by lowering of the blood pressure through either psychic or afferent nervous reflex action. Also treatment, aside from hemostasis was then directed mainly toward overcoming the nervous depression by rest, wrapping in blankets the giving of stimulants and hot drinks and the application of heat externally.

The administration of fluids for the purpose of increasing the circulating blood volume and the body fluids of the tissues at that time

received remarkably scanty consideration in terms of future developments. In 1831 Thomas Latta established the feasibility of administering fluids parenterally. He treated cholera patients in a state of collapse and dehydration by the intravenous injection of large amounts of salt solution with striking temporary improvement and an occasional recovery. However there was little attempt to extend the field of usefulness of this procedure for nearly 50 years during which time there was no report of the use of saline infusion in the treatment of a failing circulation from hemorrhage.

In 1879 Kronecker and Saunderson (23) published a report entitled *Observation of the Life Saving Transfusions of Dogs with an Inorganic Salt Solution* which was so brief and convincing and had such far reaching beneficial results that it is entitled to rank as a classic in support of animal experimentation. A translation from *Die Berliner klinische Wochenschrift* of 1879 vol 16 p 767 follows:

During some transfusion experiments which were undertaken for special physiological purposes we made the noteworthy perhaps practically useful observation that a solution of 6 gm of NaCl and 0.05 gm NaOH in 1 L of water such as Gaulle used for anastomosis of frogs hearts rendered powerless by pure salt solution (Kronecker) is capable of sustaining the life of a dog threatened by great blood loss.

Two experiments were carried out in the following manner: A carotid artery was severed and as much blood allowed to escape as would flow out. The first dog weighing about 13 kgm lost 600 gm of blood or about 60% of the total blood volume. The second dog weighing about 7 kgm lost 275 gms of blood or 50% of the total blood volume. Since the cardiac action was then very weak in both animals they were given as much alkaline salt solution as they had lost of blood. Both dogs recovered completely and rapidly and several days after the operation all traces of effect of the hemorrhage had disappeared. Cats appear not to tolerate transfusions of this solution.

Two dogs bled out from a divided carotid artery and then transfused with an amount of salt solution equal to the blood loss recovered

From an analysis of his experiments, Crile was of the opinion that the most important cause of shock was paralysis or exhaustion of the vasomotor center as a result of nerve impulses set up in the injured field. He was unable to produce fall in blood pressure by direct injury to nerves and more frequently produced increase in pressure. In none of the experiments could it be said that a response to nerve stimulation was the sole cause of the fall in blood pressure. Hemorrhage was regarded as of great importance in the causation of shock in major operations and injuries. Deep anesthesia was also found to increase the amount of circulatory embarrassment or failure. When local anesthesia was used he thought that impulses harmful through their effects on the vasomotor centers were blocked and that the circulation was less embarrassed than when general anesthesia was used. Damage of tissues from anemia was regarded as of great importance and the central nervous system was the structure that suffered most.

In the treatment of experimental shock Crile found that intravenous administration of salt solution was beneficial but that in severe injuries and operations it was ineffectual. He thought that prevention of shock was the goal to be aimed at and stressed the necessity for careful hemostasis and handling of tissues and wherever possible the use of local instead of general anesthesia.

Crile later developed a plan of treatment for the elimination of shock based on the theory of anoci association. By the blockage of nerve impulses with local anesthesia elimination of psychic influences by suggestion performance of the operation presumably unbeknown to the patient and support of the circulation by fluid administration a shockless operation was attempted.

Many of his theories were highly speculative and have not stood the test of time but his recognition of the importance of hemorrhage and his introduction of a successful technique for blood transfusion were a great stimulus for future work which has helped to place the treatment of shock on an enormously improved basis.

Blood transfusion was obviously the logical treatment for shock in which there was great

loss of blood however despite success in dogs the high incidence of transfusion reactions in man made it a dangerous procedure that in the past had been rarely attempted. It was only after the discovery of isoagglutinins by Landsteiner in 1900 and the subsequent establishment of the four blood groups by Jansky and Moss that blood transfusion became a relatively safe procedure. In 1907 Crile performed blood transfusions on the dog by direct cannula anastomosis of artery with vein, and later used this method successfully in man by anastomosis of the radial artery of the donor to a forearm vein of the recipient. Freund, Bordet and Gengou observed in animal experiments that the coagulation of blood collected in a paraffin or vaseline coated vessel was markedly delayed. Curtis and David worked out a successful technique for transfusion on dogs using a paraffin coated glass flask with two cannulas at the lower end for connection with donor and recipient. The blood was drawn into the flask and then forced into the recipient by pressure from a syringe attached to the other end. It was subsequently used with success in human transfusions. Kimpton and Brown modified the apparatus by leaving off one cannula. After drawing blood from the donor, the cannula was withdrawn and quickly inserted into the recipient without the occurrence of clotting. After successful tests on the dog this technique was applied to man and remained in extensive use for many years.

The syringe-valve methods of transfusion were similarly worked out on dogs and after their safety had been established they were used on man.

The introduction of sodium citrate for the prevention of coagulation was the last great step in the establishment of safety and practicability of blood transfusion. It had long been used in a 1 per cent solution as an anti-coagulant for blood drawn from experimental animals. Agote in 1915 and independently Lewisohn in 1915 perfected the technique determined the toxicity and standardized the dosage in citrate transfusion performed first experimentally on dogs and then on man. Since then the citrate method has come to be almost universally adopted for the performance of blood transfusion.

During the period of World War I there was still a great deal of confusion as to the causes of surgical shock which helped to retard the employment of efficient methods of treatment. For this reason there was not full utilization of blood transfusion which had just then become available for the treatment of shock. Animal experimentation carried out after World War I and during World War II was of great importance in more accurately establishing the causes of shock and improving methods of treatment.

The three factors that were considered of greatest importance in the production of shock were local loss of fluid from the circulation, nerve impulses, and toxins formed in the damaged tissues. Experiments 3 4 5 27 28 29 37 38 carried out under anesthesia principally on dogs and to a lesser extent on cats and other animals have since established the fact that by far the most important cause of shock is extensive local loss of blood, plasma or both from the circulation. Local fluid loss causing shock was accomplished by bleeding limb trauma, prolonged constriction of a limb in testicular constriction or manipulation and burning. Calculation of the amount of fluid lost has shown that in animals healthy at the start of the experiment it is sufficient to be either the principal or the sole cause of shock.

Animal experimentation has served to detract from rather than to augment, the nervous theory of shock. Traumatic and electrical stimulation (16 30) of somatic nerves, as the sciatic, of anesthetized normal animals may be carried on for prolonged periods without causing a fall in blood pressure or shock. Wang (36) reported that sciatic nerve stimulation in a dog suffering from bleeding will lower blood pressure and produce shock but not so in an unbled animal. If in a dog experiment (31) the common iliac artery is ligated and the limb pressure lowered thereby to 50 to 70 millimeters of mercury the limb may be hampered as much as 25 per cent more than is necessary to produce marked swelling and shock in controls without the initiation of shock. There is, however, marked injury to nerves and the flow of impulses should be equal to or greater than that from the hampered limb without arterial ligation conse-

quently the reason there is no shock is that there is not enough hemorrhage into the limb to produce it and not because of lack of nerve impulses from the traumatized field. Spinal anesthesia in dogs, while lowering the blood pressure to an average of 75 millimeters of mercury protects from limb trauma shock (15 31) but the protection is not from blocking a flow of nociceptive stimuli from the traumatized region, but from lowering the blood pressure which reduces by about 50 per cent the amount of blood lost when the limb is traumatized. The only purely neurogenic experimental method of producing shock is to stimulate the cardioaortic or carotid sinus depressor nerves (32 33) but in order to result in shock the blood pressure must be kept there by at low level for hours, a condition that never happens from operation or injury in man.

As a result of recent animal experimentation, the tissue toxin theory has fared as badly as the nervous theory. The shock of the crush syndrome appears to be due not to toxins but principally to loss of plasma into the limb after release of the compression as shown by the dog experiments of Duncan and Blalock. Roome and Wilson found that if the tissue juice expressed from the traumatized limb of one dog was circulated in a heparinized dog no significant fall of blood pressure or shock followed as might be expected were it to contain toxins.

The effect of animal experimentation showing that blood and plasma loss is the outstanding cause of shock and that nerve impulses are of minor importance has been to increase enormously the use of blood and plasma in the prevention and treatment of shock in man. The results have been little short of revolutionary as may be seen by reference to their use in both civilian and military practice. By their preoperative employment, patients who were either greatly debilitated from disease or in acute circulatory failure from loss of circulating fluid have been resuscitated and put into condition to tolerate operation when it was necessary. During operation careful track is kept of the amount of blood lost and in all major procedures it has become routine to transfuse blood simultaneously in amounts equal to the blood loss. Because of this pro-

cedure it has become possible to perform successfully operations that are two or three times as extensive as those that could be done before. This has resulted in great expansion of the field of operative surgery and great improvement in surgical results. Patients have been saved from extensive injuries and burns which were almost invariably fatal before the inauguration of extensive blood and plasma transfusions.

Animal experimentation has been of importance in the development of blood substitutes which may be of great assistance in emergencies where blood is not available. Ivy and co-workers carried out studies in which dogs were bled out from the carotid and the volume of blood lost was replaced by various blood substitutes except in a control series where the mortality from the hemorrhage amounted to 84 per cent. The mortality was reduced by the replacement with different blood substitutes to the following levels: saline to 58 per cent, pooled serum to 26 per cent, heparinized plasma to 6 per cent, and gelatin causing the least pseudo agglutination in vitro to 40 per cent. Citrated plasma and citrated whole blood and gum acacia and pectin solutions when given volume for volume were toxic and caused death in a high percentage of cases. Adams and co-workers have pointed out that citrated blood and plasma are rarely given for the treatment of hemorrhage in man at a rate greater than a liter per hour and in this dosage the citrated blood is not toxic. Gelatin solutions for the treatment of shock were introduced by Hogan in 1915 on the basis of experimental studies on rabbits. Levinson and co-workers have recently reviewed the literature and reported on the use of gelatin in the treatment of shock in dogs produced by graded hemorrhage. It worked so well that they did not hesitate to recommend its use in man.

Gum acacia was first used for blood replacement in experimental animals by Czerny in 1894. This caused Hurwitz to use it in a 6 per cent solution for the treatment of shock in man. Acacia solutions were extensively employed for years and many good results obtained but the relatively great incidence of toxic reactions has caused them to be abandoned for blood and plasma.

There have been numerous and conflicting recent reports on the use of saline for the treatment of hemorrhage wound trauma and burns. Animal experimentation has shown that the use of heat may be detrimental in the treatment of shock. Blalock and Mason (6) found that cooling the traumatized limb of dogs reduced the incidence of shock. Cleghorn found that when the environmental temperature varied between 72 and 95 degrees the severity of the shock from hemorrhage or trauma in dogs varied directly with the temperature.

Studies on animals have been made of the effects of various drugs that have proved to be successful stimulants in the treatment of shock, as epinephrine, ephedrine and caffeine citrate and their doses standardized. Oxygen consumption was shown to be decreased in shocked animals by Aub. This established the basis for oxygen therapy which has proved so beneficial that it has become a routine in the treatment of shock.

Various general anesthetic agents have been administered to animals in shock produced by hemorrhage, trauma, and bowel strangulation and comparison made of the way in which they are tolerated. Evans and Beecher (13) reviewed the literature and reported experiments which showed that in dogs in shock from bowel strangulation and plasma loss into the abdomen, the anesthetics employed ranked as follows in order of preference: ethylene cyclopropane, nitrous oxide gas and ether. On the strength of the experiment, Beecher recommended that either cyclopropane or ethylene should be the anesthetic of choice for operation on a patient in shock or approaching shock. Evans (13, 14) subsequently studied the influence of intravenous sodium pentothal and of chloroform on dogs in shock from muscle trauma or intestinal strangulation. They were both inferior to ethylene and cyclopropane when used during resection of the strangulated loop of bowel but intravenous sodium pentothal was no more toxic when administered even for 3 or 4 hours to the shocked dog that was not subjected to an operative procedure.

The blood bank which has played such an important rôle in the treatment of shock had

its beginning in Russia in 1928 with the studies of Shanov on the use of preserved blood of dogs. Skundina and Barenbaum demonstrated in experiments on dogs that the blood in the vessels of cadavers kept at zero temperature for 6 to 7 hours preserved its vital properties and that when transfused it participated in gaseous exchange in a normal manner. This demonstration led to the collection of citrated human blood for subsequent transfusion purposes. The result was a rapid evolution of the blood and plasma bank which has spread throughout the world and become an essential unit in every hospital for the proper control of shock.

A COMBINED PERINEAL AND ABDOMINAL OPERATION FOR THE REPAIR OF RECTAL PROLAPSE

J ENGLEBERT DUNPHY M.D. F.A.C.S. Boston Massachusetts

THE term rectal prolapse is commonly used in reference to three distinct conditions (1) simple prolapse of the rectal mucosa (2) intussusception of the sigmoid colon into the rectum and (3) true prolapse or procidentia of the rectum a condition invariably associated with a herniation of the pouch of Douglas. It is only with the last named entity that this paper is concerned.

True rectal prolapse or procidentia develops as a herniation of the pelvic peritoneum. It is associated with a defect in the transversalis fascia and a weakening and elongation of the suspensory ligaments of the rectum (6, 8). As the peritoneal pouch descends it carries with it the anterior rectal wall as in any sliding hernia. Gradually by constant pressure the secondary support of the rectum provided by the levator ani is thinned out, the anal sphincter relaxes, and the mass protrudes through the anal canal. For a while by contraction of the levators the mass may be reducible but in time these muscles become so weakened that manual reduction is necessary. In neglected cases the mass protrudes on the slightest exertion and the sphincter muscles become so atrophic as to appear to be paralyzed.

In the surgical treatment of this condition two principal approaches have been used—the perineal and the abdominal. The basic difficulty with the perineal approach is that it attacks the defect at the wrong end. Even the more extensive operations do not completely eradicate the hernial pouch or close the defect in the transversalis fascia. Of the various abdominal operations the Moschcowitz procedure as originally described is well conceived (6). It attempts to obliterate the hernial sac and to suture the defect in the endopelvic fascia, a point emphasized by Moschcowitz but frequently neglected today. But there are

two reasons why the Moschcowitz operation has not been uniformly successful. The first of these is the inherent difficulty in reaching the defect in the fascia from above without actually mobilizing the rectum. Certain modifications of the Moschcowitz operation (4, 5) attempt to overcome this objection but even when the rectum is mobilized the transversalis fascia and suspensory ligaments in some subjects are deep in the pelvis and hard to suture. The second difficulty with the abdominal approach is that the frayed out levator cannot be sutured and a long redundant rectal loop still tends to prolapse. In such cases some type of perineal repair is necessary also. It is an interesting fact that in half of Moschcowitz's original cases some type of perineal operation was combined with the closure of the pouch of Douglas.

No originality is claimed for the operation which is described in this paper. It is a more radical procedure than has hitherto been thought justifiable and one which prior to the days of chemotherapy might well have carried a prohibitive mortality. It consists of the following steps, each of which has been advocated by others: (1) by the perineal approach—(a) circular amputation of the prolapsed segment of rectum (3), (b) excision of the redundant hernial sac, (c) suture of the levators anterior to the rectum (1, 2). (2) by the abdominal route—(a) mobilization of the rectum and suture of the transversalis fascia (4, 5), (b) obliteration of the hernial sac and closure of the pouch of Douglas by circular suture (6), (c) fixation of the pelvic colon to the lateral wall of the pelvis (7).

TECHNIQUE OF OPERATION

As soon as the diagnosis is made, the patient is advised to keep the mass reduced as much as possible and to strengthen the anal sphincter and levator ani by frequent regular voluntary contractions. He is told literally to con-

tract his sphincter one thousand times a day. The importance of this maneuver can not be overemphasized. Tone can be restored to the anal sphincter by voluntary contraction as in any skeletal muscle which has become atrophic from disease. The patient is hospitalized for approximately 1 week prior to operation during which time these measures are continued and the bowel is prepared by the administration of sulfasuxidine or sulfaphthaldine in appropriate doses.

The perineal operation is performed first. Spinal or general anesthesia may be used. With the patient in the lithotomy position the prolapse is drawn down and a circular incision

is made in the rectal mucosa about 0.3 centimeter above the pectinate line (Fig. 2). As this incision is deepened, the outer loop of bowel may be peeled off the inner loop thus exposing the hernial sac (Fig. 3). The relationships are shown diagrammatically in Figure 4. The size of this pouch of peritoneum varies but in all of our cases it has been large enough to be dissected off the bowel as a distinct sac (Figs. 5 and 6). The sac is then opened and the neck is closed by circular sutures as high as these can be conveniently placed (Fig. 7). The redundant sac is then excised (Fig. 8).

The sac is then pushed upward and as the anterior rectal wall is depressed with the

Fig. 7 Circular suture at apex of the peritoneal sac.

Fig. 8 Excision of the excess peritoneum.

finger sutures are placed in the levator muscles lateral and anterior to the rectum (Figs 9 and 10) Good firm muscle can be secured in these sutures. Two or three No. 1 chromic catgut sutures are used to bring a firm barrier across the perineum below the amputated hernial sac and anterior to the rectum (Fig. 11).

The tube of rectum is then split anteriorly and posteriorly (Fig. 12) and traction sutures of fine silk are placed through the entire wall of the bowel uniting it to the distal 0.3 centimeter cuff of rectal mucosa which was left above the pectinate line (Fig. 13) The two halves of the bowel are then excised and two

lateral traction sutures are placed (Figs 14 and 15) These sutures are tied and the remainder of the anastomosis is completed by a continuous lock stitch of fine catgut which is interrupted and tied as it reaches the mattress sutures (Fig. 16) It is important not to complete the anastomosis with a continuous circular suture because the cinching effect of this suture tends to narrow the canal.

The abdominal operation is done as a separate procedure some days later. The abdomen is opened through a midline suprapubic incision. After the pelvic peritoneum is incised on either side of the colon the bowel is mobil

ized exactly as in an abdominoperineal resection. It is comparatively easy to do this without injury to the blood supply. After mobilization of the bowel deep sutures are placed including the pelvic peritoneum and the fascial and ligamentous tissue lateral to the rectum. The remainder of the pouch of Douglas is then closed by circular sutures as in the original Moschcowitz operation. Finally the pelvic colon is anchored to the left lateral wall of the pelvis by several interrupted sutures of fine silk. The condition before and after the combined operation is shown diagrammatically in Figures 1 to 17.

RESULTS OF OPERATION

The operation as described, has been performed in 4 patients. The periods of observation since operation have been 1 year and 8 months, 1 year 8 months, and 4 months, respectively. There have been no recurrences. One patient developed an abscess anterior to the rectum and slight retraction of the rectal mucosa at the site of the anastomosis. Moderate stenosis of the anastomosis was controlled by daily digital dilatation. At present, this patient is getting on well without further dilatation. All the patients are continent. Two patients have returned to active life after hav-

Fig. 17. The relationship at the completion of the operation, showing the remainder of the sac to be obliterated by the abdominal operation.

ing been incapacitated by complete rectal procidentia for periods of 11 years and 2 years respectively.

The perineal part of the operation alone was performed in a fifth case. Because of the advanced age of the patient, 72 years the abdominal operation has been postponed in definitely. It is now 8 months since operation and no tendency to recurrence has appeared.

In a sixth case a combined abdominal and perineal operation was performed but the abdominal operation was done first and the perineal procedure consisted of posterior fixation of the rectum to the sacral fascia. This

patient has remained well for over 7 years since operation.

DISCUSSION

The great variety of operative procedures still recommended for the treatment of rectal procidentia indicates considerable dissatisfaction with the end results. A study of 12 cases in which patients were operated on in the Peter Bent Brigham Hospital between 1914 and 1938 confirms this impression. In 5 the Moschcowitz procedure alone was employed. There were 3 recurrences. In 3 some type of perineal repair was employed with 1 recurrence, 1 cure and 1 fairly satisfactory result.

In 3 cases both the Moschcowitz operation and some type of perineal repair was performed but the second stage was not carried out until a sizable recurrence had followed the first operation. One of these patients died following the second operation. In the 2 others the end result was fair in 1 and a complete failure in the other.

It would be premature to suggest that a combined perineal and abdominal repair is the final answer to the problem of rectal prolapse. To date the results in our cases have been very gratifying and the procedure despite its magnitude seems worthy of further trial. In early cases before the levator muscles and anal sphincter have been frayed out by constant pressure a repair from above which tightens the suspensory ligaments, closes the defect in the transversalis fascia and obliterates the pouch of Douglas would seem to be sufficient. However in advanced cases some type of perineal repair with suture of the weakened levators should be combined with the abdominal approach.

It has not been established that the perineal repair should be done first. Equally satisfactory results might be obtained by first per-

forming the Moschcowitz operation and then repairing the levators from below without amputating the rectum. This would have the advantage of being a cleaner operation and would eliminate the anastomosis at the anorectal line.

Although the results to date have been excellent this paper should be regarded as a preliminary report. The best solution to this distressing problem still must come from further observation and study.

SUMMARY

The technique of a radical operation combining features of both abdominal and perineal repairs for rectal prolapse is described. The complications and results of this operation are presented.

OBSTETRICS IN THE SMALL GENERAL HOSPITAL

CHARLES E. CONNER M.D., Cashmere, Washington

THE literature contains many reports of obstetrical analyses. Nearly all of these come from large clinics and hospitals, the great majority from the eastern United States. A personal interest in statistical comparisons was the stimulus for this paper the purpose of which is to present the findings in the obstetrical services of two small general hospitals in the Pacific North west. For many reasons statistical comparisons proved to be nearly impossible. But it is the author's opinion that the results from this community are of interest *per se*.

The analysis is based on the hospital records of 2 500 consecutive mothers delivered in the two general hospitals in Wenatchee Washington during the years 1944 1945 and 1946. The city has a population of about 13 000 and serves medically a population of approximately 50 000 almost all of whom are white. Both hospitals are church directed one Catholic, the other Protestant. One has a rated capacity of 55 beds, with 20 bassinets the other 75 beds and 20 bassinets. Due to the war and to population increases in the area, both institutions ran at 90 to 120 per cent of rated capacity during the 3 years, with a resultant strain on the medical and nursing personnel and space to care for obstetrical patients was a constant problem. Both hospitals are approved by the American College of Surgeons.

They were staffed during these years by 30 physicians 24 of whom practiced obstetrics. There were 2 obstetrical specialists in the group the majority of the deliveries being done by general practitioners. There are no interns or residents in the hospitals.

Statistics regarding ectopic gestation and abortion in patients who were cared for in the hospitals are not included in this paper. It may be assumed that an average amount of prenatal care was given the patients for in general the class of people is high and the value of prenatal care is not underestimated by the physicians of this community. The incompleteness of some of the hospital rec-

ords due to war time pressure however made the preparation of this paper more difficult. It is comforting to find the more recent records much more complete.

In this series, there were 16 pairs of twins delivered an incidence of 1 in 156 deliveries. In this group there were 5 maternal deaths a mortality of 0.20 per cent. This figure may be compared with the maternal mortality for the United States for the year 1940 as prepared by the U.S. Department of Labor (4) of 0.376 per cent. In the same report the State of Washington has a rate of 0.306 per cent 18th in the United States. Newberger, analyzing obstetrical statistics in the State of Illinois during 1943 found a maternal mortality rate of 0.27 per cent in hospitals which had a comparable number of deliveries.

Of the 5 deaths here reported 1 was due to shock and hemorrhage following vaginal delivery of a placenta previa 1 due to acute yellow atrophy 1 to severe rheumatic endocarditis 1 to diabetes mellitus and 1 of a patient in the first stage of labor to ruptured myocardium. Although comparisons may not be made with complete fairness and although this series is admittedly small it is the author's opinion that the mortality rate in the Wenatchee hospitals is very low and speaks well for the care which a general practitioner and a general hospital may give to an obstetrical patient. This is especially true when one considers that there were no deaths nor any serious complications from puerperal sepsis or toxemia. These two complications account for over 60 per cent of the maternal deaths in the United States.

The infant mortality rate here was also comparatively low though less strikingly so. There were 82 infant deaths an overall mortality rate of 3.28 per cent. Of these 28 were stillborn 1.12 per cent of the total babies born. Stillbirth accounted for 34.2 per cent of the total infant deaths. Of the neonatal deaths 24 or 53.7 per cent were due to prematurity (under 30 weeks pregnancy). An analysis of infant deaths appears in Table I.

TABLE I.—INFANT DEATHS

*Per cent of neonatal deaths (in age of the hospital only in which an epidemic of infant diarrhea occurred)

The relatively low maternal and infant mortality figures given invite an analysis of the treatment of the various major complications of pregnancy. The incidence of the major complications in this series appears about average, although it is my opinion that some cases of pre-eclampsia, essential hypertension, and chronic glomerulonephritis were not reported on the hospital charts as such.

PRE ECLAMPSIA

There were 5 cases of pre-eclampsia, 0.20 per cent. In this group 3 cesarean sections were done, with 3 live mothers and infants. In one case of vaginal delivery of a premature infant, death of the infant resulted, in another mother and child both lived. In these cases marked albuminuria and hypertension were present. Attempts at medical control of the symptoms were unsuccessful. That there were other cases of mild pre-eclampsia, unreported on the charts, appears likely.

ECLAMPSIA

Three patients with eclampsia, 0.12 per cent of the total obstetrical cases were delivered 1 by cesarean section in which instance

mother and child survived 2 vaginally (induced labors) in which premature infants died. All 3 of these mothers had antepartum convulsions. None had any noteworthy postpartum complications. The patient delivered by cesarean section had not had antepartum care and was first seen with epigastric pain and muscular twitchings with two convulsive seizures while under anesthesia.

No cases of essential hypertension or chronic nephritis are recorded. There was 1 maternal death, immediately following delivery of a healthy infant, due to acute yellow atrophy of the liver. This mother had had hyperemesis gravidarum during most of her pregnancy and was first seen here when in active labor.

The incidence of cesarean section in toxemia in our group (4 out of 9 cases) is high. It is likely that some or all of these mothers might have survived vaginal delivery (all were primiparas) but the happy ending for mother and child in these deliveries speaks for itself.

PLACENTA PREVIA

Eighteen cases of placenta previa were delivered, an incidence of 0.74 per cent of total deliveries. 6 were complete and 12 partial or marginal. Eight patients were delivered vaginally with 1 maternal death, due to shock and hemorrhage. All the infants lived. Ten patients were delivered by cesarean section all but 1 of whom were in labor and were bleeding. In this group all the mothers and all but 1 of the infants survived. Six of the 10 patients were primiparas. One of the patients, a primipara, who was delivered vaginally died. The maternal and infant mortality rate for placenta previa in this series was 5.5 per cent.

ABRUPTIO PLACENTAE

There were 3 cases of abruptio placentae an incidence of 0.12 per cent, without maternal death. One patient was delivered vaginally 2 by cesarean section. One of the babies delivered by cesarean section lived the other and the one delivered vaginally died.

CESAREAN SECTION

Of the 2500 deliveries, 74 were by cesarean section an incidence of 2.96 per cent. In this

TABLE II.—INCIDENCE MORTALITY AND INDICATIONS FOR CESAREAN SECTION

Incidence	Arnold Per cent	Chicago Lying-In Per cent	Barnes Per cent	Wenatchee Per cent
Maternal mortality	20			
Infant mortality	1.00		0	0.00
Cephalopelvic disproportion	0.8		7	0.00
Previous cesarean	5.3	26	20.8	40.3
Placenta previa	7	7.0	20	3.3
Cervical stenosis	20.6	7.0	0	3.3
Torsion	4.0		4.8	6.7
Malposition of fetus	7	3	7.6	2.3
	8.8	7		3

regard an examination of the literature is most interesting for the reported incidence of abdominal deliveries varies greatly. In general it seems to be much higher in private than in charity institutions. The lowest incidence found in the reports here reviewed was 1.50 per cent reported by Arnold. Others varied up to 16.1 per cent the general average appearing to be between 2.0 and 3.0 per cent. There were no maternal deaths in the Wenatchee series but the number is too small to be of value in comparison with other reports.

The circumstances under which the cesarean sections were carried out are of considerable interest. Table II gives the reasons for the sections compared with indications in other series. The chief discrepancy between the Wenatchee figures and those of others lies in the relatively high incidence of cephalopelvic disproportion as an indication for abdominal delivery. Our figures show 49.3 per cent done for this reason the highest other figure being 36 per cent. This disproportion however is more likely apparent than real. We have no adequately accurate method of relative measurement of the maternal pelvis and fetal head (if there really is one) and the obstetrical judgment as to the lack of progress of labor. In questionable cases this is probably as good a criterion as any. It is the consensus here that, if there is real doubt as to the adequacy of a pelvis it is better to do a section before the mother is exhausted and the fetus is dead. In this small series at least the results seem to justify the means.

In 20 of the 74 cases cesarean section was carried out by an obstetrical specialist. Of these all were laparotomies. The remainder (54) were done either by general surgeons or general practitioners who do obstetrical surgery. All but 1 of these were classical. One was a hysterectomy for fibroids and bicornuate uterus following classical section.

The low maternal and infant mortality rate in the cesarean sections here reported speaks well for the staff. The relatively few low cervical sections done perhaps do not. Only the obstetrical specialists did low cervical sections. There has been a good deal of argument locally about the relative values of the two

types of cesarean section. Most of the surgeons have held that the ease of performance and speed in doing the classical section outweigh the advantages of the low cervical section. One or two of them however are changing their minds since the figures for this report were compiled. Others will likely do so. Of further interest is the fact that there were no cases of peritonitis following cesarean section—this in spite of the fact that several sections were done more than 24 hours after the membranes had ruptured. Penicillin and the sulfonamides are probably responsible for the absence of peritonitis in some of these cases. Whole blood transfusions were used when indicated but not in the majority of cases.

SUMMARY

For comparative purposes the results of 2500 consecutive deliveries by general practitioners and obstetricians in two small general hospitals are presented.

A brief review of comparable statistics from the literature is given.

The relative incidence of low cervical sections to classical cesarean sections done in this community should be increased.

The general practitioner in a small but well managed general hospital can secure excellent results in obstetrics.

PRIMARY CLOSURE OF HARELIP

THE attempted closure of congenital lip clefts dates back to surgical dawn and the *do s* and the *don s* that guide us today had been well established in the first half of the past century but with the distracting introduction of anesthesia and the control of sepsis these gains were mostly lost in the latter half of the same century and largely neglected during the first quarter of the present. It is temptingly easy to freshen and unite the cleft borders, but that it takes skill and real study of each individual case to obtain an acceptable result has been rather commonly overlooked. In this type of surgery the margin between success and failure is narrow pitfalls are numerous, and luck, if any is mostly bad. Further the area is always in evidence and ironically it is the poor results that attract attention while the factor of an excellent outcome must content himself with the silent

flattery of non recognition. We now see children raised in utter ignorance of an early correction.

The primary aim of any operative plan is to retain free breathing and produce a symmetrical lip and nose of natural appearance without too evident suture marks or other scars. Undue transverse shortening, vertical over length, or both asymmetry of the lip or vermillion or failure to correct vestibular distortions are the more common faults of planning or execution that make for the not pleasing result.

With any congenital lip cleft, partial or complete, there is some actual deficiency of lip tissue but most of the spread of a complete cleft is due to tissue displacement. The first operative move to be undertaken only after sufficient study checked by the use of measuring dividers is to ink in the pattern of cuts that will determine the contour of the nascent lip and nose. Previous study will have also estimated the amount of lip, cheek, and nasal mobilization needed to permit soft tissue adjustments without undue tension. In a primary operation this is made available by simple undermining the extent of which is determined by the needs of the individual case.

The infant's condition and related circumstances are apt to dictate the operative *when* the operator's fancy and the extent of involvement will largely determine the *how*. As a general rule the earlier the simpler. Lip closure in the first two days of life makes possible exhibition of an apparently normal infant two weeks later which is a great comfort to a mother who has by then weathered the first shock. Barring this very early closure simpler operations will still suffice any time be-

tween two weeks and two years later as circumstances dictate without resorting to the more extreme measures

In the baby with partial cleft the undermining might be quite limited but for a wide spread opening in one of similar age the complete cheek mobilization might extend the full depth of the maxilla and up to the orbital border on the cleft side somewhat less on the other. Also corresponding liberation of the ala plus undermining between the skin and lower lateral cartilage through a transverse intranasal incision made along the upper edge of the lower cartilage and in addition some slight trimming of the alar border anteriorly might be needed to raise it. All of the above is to insure proper airway and contour

In early childhood the unoperated upon or maladjusted lip can develop a definite droop as well as increased backward displacement of the ala which demands repositioning by completely separating the two halves of the columella, free undermining of the skin over and beyond the upper lateral cartilage with removal also of a triangular piece of skin and cartilage from just above the alar border. It will take all of this and maybe more to raise the slumped ala to its proper position. This new molding is maintained by suturing

In adolescence faulty or non approximation may have caused lateral divergence of the nose from the cleft side which if sufficiently disfiguring may require complete subcutaneous chisel or saw mobilization and mass fixation with trans-tissue wiring of the freed nasal spine to an upper molar tooth. This to be retained for four to six weeks. The above progressive complexities emphasize the advantages of early correction

There are four merging types of classic single harelip, the partial soft tissue cleft the complete soft tissue cleft the complete lip cleft involving also the alveolar process and

the very wide complete cleft of lip and palate. The first of these can be the most refractory because of sparsity of excess vermilion complicated by a small transverse nostril while the wide open cleft is vermilion lined and the ala is stretched. Regarding the alveolar or the complete bony cleft in the vast majority of cases the separated borders will be quickly drawn together with slight overlapping after any sort of lip closure. This narrowing of the bony cleft is helpful to the subsequent palate closure but it leaves an opening in the upper fornix to be closed at the time of the staphyloplasty or later. Very rarely is the bone resistant to the lip pressure. Forceful approximation of the bony cleft borders is a mutilating practice condemned by writers of the early 19th century revived by dentists in the 1840s of the 90s but happily now almost extinct

There are two general plans of closing the lip-nose cleft, each capable of special modification. The earliest is the Husson Rose plan which eliminates the straight or convex cleft borders by angular or curved excisions which when sutured push upward and downward in a straight line. The length of the line will depend upon the depth of the excision but this procedure is apt to give too long a lip. The second plan more difficult but more adaptable is best represented by Mirault's presentation published in 1844. It consists in preserving an angular flap taken from the upper part of one side of the cleft across the defect and uniting it to the denuded opposite border. Regardless of the type of excision for the tissues that are to be sutured to a vertical line the vertical part should be beveled so the tension will be on the deep-holding sutures with no strain on the superficial ones. In that way possibly with the help of a little radium unsightly scars can usually be prevented

The lip closure of complete double cleft of lip and palate is done in two steps. At the

first step closure is accomplished by adjusting the widespread alae and suturing the upper part of the Rose or Mirault sectioned lateral lip fragments to corresponding areas of the denuded prolabium. So far the procedures are similar. Lower down in the Rose type the prolabium is trimmed to a point, but in the Mirault plan it is cut squarely across if the lip flaps are to interdigitate or to a blunt point if the flaps are to be trimmed to abut in the midline. The cheek ala undermining for the above is greater than in the single cleft for there is no appreciable length to the columella and the premaxilla stands well forward of the maxillae. The septum is not to be shortened at this stage. Doing so might risk letting the premaxilla drift back between the maxillae which is ruinous to both incisor occlusion and to facial contour.

Second step. The premaxilla push back done at the hard palate closure will have caused definite nasal snubbing. Correction of this consists in raising a superficial trifoli flap from the lip in conjunction with the separation of the short columella from the septum. A far forward transverse cut across the septum will then permit the nasal tip to be advanced and leave a corresponding triangular defect in the septum. Sutures the lateral leaves of the trifoli into the septal defect on each side and closing the lip defects will restore continuity to the advancement.

The double clefts may be mirror images or either cleft might fall into one of the four types mentioned above.

In the complete double cleft the premaxilla will be found at the tip of the nose. If there is any attachment between the maxilla and premaxilla on either side no matter how slight the central mass will diverge in that direction. A bilateral attachment, no matter how attenuated will restrain the forward movement of the mass.

There are few primary instances of harelip in which an acceptable result cannot be attained in from one to three operative steps. There are still fewer in which the original possibilities can be attained after a bungled start.

VILRAY P. BLAIR

ROBERT R. ROBINSON

CONGENITAL ATRESIA OF INTESTINE AND COLON

ATRESIA of the bowel is a rare congenital deformity which obviously cannot be diagnosed until symptoms of obstruction appear. Vomiting is the first symptom but since some vomiting in the newborn is not abnormal its significance for a time is not appreciated. If the obstruction is high persistent vomiting will begin shortly after birth. If the obstruction is near the ileocecal valve the most common site vomiting may not become alarming until the second or even the third day of life. Most atresias of the bowel are distal to the ampulla of Vater; the vomitus therefore is green. A newborn baby who vomits green material has intestinal obstruction until proved otherwise. It does not have pyloric stenosis because the vomitus of a baby with pyloric stenosis is never green.

Distention of the abdomen likewise varies with the level of obstruction. Gastric peristalsis moving from left to right may be observed in obstructions of the duodenum or the beginning of the jejunum. One should not be led astray by finding a scaphoid abdomen in these patients. Progressive and finally marked distention of the abdomen however typifies atresias of ileum or colon. Intestinal patterning is usually visible.

The difference between a normal meconium stool and that of an infant with intestinal atresia is not great enough to be impressive. The nurse's notes usually show a record of

'meconium stool. Only one who has had rather extensive experience in the care of infants would notice and realize the significance of the fact that a baby who was vomiting green material had a stool which was smaller in amount lighter green in color and was firmer in consistency than the usual normal greasy consistency tarry meconium stool.

The suspected diagnosis of atresia of the intestine or colon is easily confirmed by examination of roentgenograms made of the baby in the upright position. Widely distended loops of bowel showing fluid levels will be seen. The number of distended loops of bowel and their position in the abdomen will indicate the level of obstruction. These babies should not be given barium; its use is unnecessary for diagnosis; it tends to clog the intestine and if aspirated produces tracheobronchitis.

The treatment of congenital atresia of the intestine and colon is surgical. It is trite to state that the earlier in life these obstructions are corrected the better the results will be and yet at the same time it is advised not to rush these infants to surgery until two conditions are met: first dehydrated infants must be restored to near fluid and electrolyte balance by intravenous administration of isotonic solution of saline 10 to 15 cubic centimeters per pound of body weight plus 50 to 75 cubic centimeters of 5 per cent dextrose solution per pound of body weight. This amount of fluid is sufficient for 24 hours. What part of it is given before surgery is a matter of judgment in each case. Second the stomach must be thoroughly emptied before operation. This is usually accomplished by inserting a No. 10 French catheter into the stomach through a nostril and aspirating with a syringe. The catheter is left in place during operation and following surgery is attached to a Wangensteen suction apparatus.

The operation on these infants is best done under open mask ether anesthesia. The abdomen is opened through a right rectus muscle splitting incision. If the distended loops of bowel are allowed to escape spontaneously from the abdomen there will be little trauma and the pathological condition will be found easily and rapidly. From the point of atresia the undeveloped bowel is followed distally to the rectosigmoid in a quick search for other obvious atretic areas. If none is seen a fine needle is inserted into the lumen of the collapsed bowel and salt solution is injected to demonstrate possible points of atresia; no vision will serve to distend the small caliber bowel and to soften any unspissated material. A large needle attached to a 50 cubic centimeter syringe is then inserted into the distended bowel at the site where the anastomosis is to be done. The distended bowel is completely deflated and as much of the meconium as possible is removed.

A side-to-side anastomosis isoperistaltic or antiperistaltic, is made between the distended and undeveloped bowel. The temptation to do just an ileostomy should be curbed because these infants do not survive ileostomies. The anastomosis is done with No. 00000 Deknatel silk on an atraumatic needle for bringing serosa to serosa and such silk or No. 0000 chromic catgut is used suturing mucosa to mucosa. The sewing must be painstaking in careful spacing of stitches and in avoiding large bites of tissue lest the lumen of the bowel be encroached upon. Although the infant may be in poor condition it should not be forgotten to close the opening between the two leaves of mesentery.

Not infrequently these children do badly during surgery. Stopping all anesthesia and giving the baby oxygen only until the peritoneum is to be closed has been a factor. I am

certain. In avoiding operating table casualties in at least two of these patients at the Children's Memorial Hospital (Chicago) A blood transfusion of 50 to 75 cubic centimeters is always given during the operation.

Following surgery the infant is placed in oxygen. Penicillin 10,000 to 20,000 units is given intramuscularly every three hours. Negative suction on the catheter in the stomach is maintained for at least 48 hours. Feedings of a dilute formula are begun cautiously and in small amounts. If vomiting or distention recur gastric suction is resumed. Food, fluid and electrolyte balance are maintained by routine fluids, blood, plasma and amigen.

Surgical mortality of congenital atresia of

the intestine and colon will always be high for the following reasons. The infrequent abnormality is apt to be overlooked until bowel gangrene is imminent. Multiple atresias of the bowel at times make anastomosis futile. Other congenital abnormalities may be present and add to the risk of surgery. However mortality statistics are tremendously better than twenty years ago. Then recovery following surgery was an oddity. Now because of chemotherapy, wiser use of proper suture material and recognition of physiological requirements a baby with single atresia of the bowel but otherwise normal has a fair chance of postoperative recovery.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

DR. CRILE was an inveterate recorder of what he did and of the things he saw and heard a confirmed transcriber of his thoughts on the problems he faced with the result that he left a world of material from which Mrs. Crile has woven a story of his life of absorbing interest.¹ Cited with descriptive ability he has left a travelogue of fascinating beauty covering the countries he visited their natives flora and fauna, their mountains valleys, and cities. But most important he has outlined the trails which he followed in research in which field he has contributed so much. Possessed of an inquiring mind he was ever asking the why and how and was never content until the answer to the problem was at hand. Coming from pioneer stock it was befitting that he became one of the pioneers of the medical frontier leaving an indelible imprint upon contemporary medicine surgery and science. Witnessing the death of his friend William Lyndman from shock started a train of inquiring thought which persisted throughout life and resulted in invaluable contributions in the elucidation of shock its prevention and its control. Out of this research came his accepted offerings on hemorrhage and transfusion.

His work in the Medical Corps of the Army during the Spanish American War and World War I is given in sufficient detail to make clear the valuable contributions he made to the Medical Department in both conflicts. The opportunities for mass observation in the latter aided greatly in his scientific research and reveal his ever incisive and inquisitive approach to scientific problems. While always a scientist and a research devotee he was a humanist with his goal the benefit of mankind and the improvement of human welfare.

His query as to what is life? remains unanswered but from a scientific standpoint he has given us much upon which to cogitate. His indomitable energy his forcefulness and his courage are revealed in his manner of overcoming the vicissitudes of fate with which he was beset and furnished an example and an inspiration to all of us who tread the same path even at much lower levels.

His study of the animal power plant undertaken through years of travel to all parts of the world including all animals from mouse to the elephant is the one comprehensive study of its kind and furnishes statistical data of incomparable value.

¹GEORGE CRILE. *AN AUTOBIOGRAPHY*. Edited, 11th ed. by Grace Crile. 2 vols. Philadelphia and New York: J. B. Lippincott Co., 1937.

The autobiography of this pioneer furnishes revelation stimulation and inspiration in disclosing the creative impulse which marked him as a man apart a man who sought an answer to the secrets of nature and who provided many answers. Undaunted he cheerfully accepted the challenge of his time and seized upon the opportunities which it afforded. His remarkable versatility is reflected in the many fields in which he was interested and in which he achieved distinction. His lofty ideals his vision for the shaping of a better surgical world can be perceived in the policies and accomplishments outlined in his life history. His devotion to the improvement of surgery was ever uppermost in his mind and efforts his part in the development of the American College of Surgeons was but an instance of this urge.

In reading this autobiography one gathers an appreciation of his rich personality his accomplishments his leadership his contributions to science, his dual capacity as a great surgeon and an original investigator pre eminent in both scientific research and surgical technique a master surgeon and scientist a benefactor of mankind. The sidelights by Mrs. Crile disclose that which one would expect a devoted husband and father with ever present love solicitude and affectionate consideration for those near and dear to him. In other words, he was a man among men, a surgeon of the world a scientist seeking knowledge.

IRVING ABELL

THE author has revised his older text *Anatomy for Physical Education* and altered the title to *Concise Anatomy*¹ for the purpose of reaching a wider range of students in fields that pertain to medicine, such as physical therapy occupational therapy medical technology nursing dental hygiene and physical education. The general plan of the book is little changed. New material on the histological and developmental aspects of anatomy is inserted and much of the applied anatomy² found in the previous text is now omitted. The illustrations few of which are original have been reduced from 472 mostly colored in the earlier work to 324 nearly all without color in this volume. The omission of color in depicting nerves blood vessels etc. has resulted in considerable loss of clarity in the illustrations.

The text is indeed concise yet the author has included many complex anatomical details in his account often without adequate descriptive background for their proper understanding. As an ex-

¹CONCISE ANATOMY. By Linden L. Edwards, Ph.D. Philadelphia, Toronto: The Blakiston Co., 1937.

ample, chapter 5 "General Neurology" consists of 54 pages devoted to detailed condensation of the developmental anatomy histology and gross anatomy of the nervous system and meninges and to an outline of the nervous pathways in the central, peripheral and autonomic nervous systems. In addition descriptions of the eye, ear and other sense organs are included. (The course and distribution of cranial and spinal nerves are described elsewhere in the book.) Several complex diagrams of nervous pathways (taken from Morris *Human Anatomy*) are inserted in the chapter. It is doubtful that the beginner will find this chapter very useful.

The reviewer is of the opinion that the reading audience envisaged in the preface to the book (and listed above) is in no position by reason of experience to appreciate a condensed treatise on embryology histology neurology and gross anatomy such as has been produced in this text.

D. V. L. B. ETT

THE more conventional plan of many treatises on the subject of general surgery is presented in *Surgery* by Rafael Urzua. It was written for medical students in the advanced grades of the University of Chile, and to them in his preface the author addresses sound advice regarding the high ideals expected of one who aspires to be the perfect surgeon.

The author has divided his material into four parts, the first of which relates to the general principles of surgery preoperative considerations, the value of a surgical team anesthesia an evaluation of the various forms of anesthetics and their modes of administration treatments of wounds burn and shock, vascular disorders, tendons nerves, and orthopedic problems including amputations.

In the second part the surgery of systems is discussed under titles of surgery of the neck, thorax, extremities, and breast, whereas such subjects as the abdominal parietes, hernia, peritoneum, digestive tract, and anorectal diseases are included in the third part.

The fourth part discusses surgery of the liver gall bladder pancreas, spleen, kidney female organs, and urogenital diseases.

The book is purposely without bibliography as the author believes surgery is learned not from books but from observing it, living it and perfected only by intense study. This book is intended to contain only general surgical principles beyond controversy. There is a generous smattering of illustrations, all of the pen and ink type which are not infrequently in distinct and imperfectly reproduced.

As far as the text is concerned the author attains the aim of his presentation as the subject matter is succinctly treated at times a single paragraph disposes an entire subject. This makes the book a teaching treatise and permits amplification of specific topics by drawing on other sources. It has a synoptic character and because of this its scope appears

exhaustive. It should serve as an excellent review for students and practitioners.

STEPHEN A. ZIRKIN

THE sixth edition of *Recent Advances in Endocrinology* comes after an interval of 3 years during the interim no major changes have been made, and save for the addition of a short section dealing with the treatment of hyperthyroidism with thiouracil and its derivatives the present issue consists mainly of an extension of previously written chapters rather than of correction. As its title implies the book is essentially a collation of current knowledge relating to the whole field of endocrinology. Each ductless gland is considered in detail, the symptomatology of its diseased states is lucidly set forth the underlying alterations in biochemistry and morbid physiology are described in detail and treatment is touched upon. The happy result is a well organized and succinct general textbook of the glands of internal secretion which should be of particular value to the student and to the beginner in the subject. The author emphasizes principles rather than details of therapy and avoids any generalizations as to treatment. Hence the worth of the book to the expert or to a practitioner engaged in following an individual case is somewhat limited. The author has succeeded most satisfactorily in epitomizing the entirety of a complex branch of medicine and his exclusion of any therapeutic dicta is therefore no doubt proper. To a minor extent the volume suffers because of its illustrations which are both old and not well reproduced.

The appearance of the present edition coincides with the death of Dr. Cameron after a protracted illness, on September 25. The author had been professor of biochemistry at the University of Manitoba since 1919 and has been recognized as a foremost authority in his field for the past three decades.

WAYNE CAMERON

THE book *The Foot and Ankle* which is now in its third edition was written with the stated purpose of doing for the foot and ankle what Dr. Hanau did for the hand, that is, to tell the general practitioner what to do for the common conditions that occur in and around the foot. The author has accomplished his purpose by creating a most interesting readable, and workable book that should prove of inestimable value not only to the general practitioner but to medical students and younger orthopedic surgeons as well. It is straightforward in style, comprehensive in scope, and contains many illustrations of good quality. The author's device of using heavy black margin blocks to summarize salient points is a great time saver and also adds to its value as a ready textbook. In general this book is organized to cover in logical sequence the embry-

RECENT ADVANCES IN ENDOCRINOLOGY. By A. T. CAMERON, M.D., M.A., D.Sc. (Edin.). F.R.C.S., F.R.S.C. 4th ed. Philadelphia, Toronto, The Blakiston Co., 1937.

CORRESPONDENCE

MEDICAL AND SURGICAL SUPPLIES DESPERATELY NEEDED IN WAR DEVASTATED AREAS

CONTINUED aid in the form of medical and surgical supplies from America is needed to prevent widespread suffering and death among the peoples of war-devastated areas throughout the world. The undersigned earnestly request all members of our profession to help us provide such aid through the Medical and Surgical Relief Committee, Inc.

During the past seven years with little publicity and modest financial support, this Committee has provided more than a million dollars worth of desperately needed medical, surgical and dental supplies and publications to stricken areas overseas. These materials are sent to hospitals, physicians and dispensaries giving free medical care to the needy.

Our colleagues in Europe and the East are still faced with an appalling lack of basic medical equipment. Some have not even seen a medical journal or textbook printed since 1939 and are woefully unimformed of many of the latest medical advances.

We are able to do a great deal to alleviate this situation through the Medical and Surgical Relief Committee which receives sorts reconductions, and ships material—ranging from physicians samples to used instruments—in response to authenticated appeals from overseas.

The items most consistently requested and most vitally needed are

- | | |
|--|---------------------------------|
| Adhesive tape | Microscopes |
| Ampuls—all types | Penicillins |
| Anesthetics (local, general) | (Crystal, Ointment, Tablets) |
| Antiseptics | Quinine—(tablets, capsules) |
| Aspirin | Rubber sheeting and tubing |
| Aspirin combinations | Santons and combinations |
| Artiodiaries | Scientific pourtrous |
| Baby { bottles | Sedatives |
| cereal | Squashed M. B. locations for vs |
| clothes | moss conditions |
| food | Sterilizers |
| supplies | Streptomycin |
| Cod liver oil | Tablets—(tablets and liquids) |
| Cotton—gauze—all forms | Surgical gloves |
| Dietary supplements | Surgical needles |
| Germicides | Surgical instruments |
| Hospital ware | Thermometers— |
| Hot water bottles and syringes | (Fever—F or C) |
| Hypodermic needles and | Vitamins—all types and |
| syringes | strengths for children and |
| Liver and iron capsules | adults |
| —and the most pressing need of all is for recent medical, surgical and dental textbooks and journals | |

Please forward any such supplies which you and your hospital can donate to this great need to:

The Medical and Surgical Relief Committee, Inc.
Room 318 430 Lexington Avenue
New York 17, N. Y.

We urge you to lend your support to this vital work!

THE USE OF THE TERM "WERTHEIM OPERATION"

The Editor: The revived interest in the surgical treatment of cancer of the cervix raises the question of terminology for the procedures employed. The use of the expression "Wertheim operation" is widespread for any procedure that is supposed to be radical for resection of the uterus and its adnexa. The question of this terminology would be of little importance in itself and would hardly justify comment were it not for the fact that it entails certain inaccuracies and confusion in the discussion of results.

In 1900 Wertheim of Vienna reported 24 operations upon carcinoma of the cervix in which some parametria was excised. In some instances the lower segment of a ureter involved by the tumor was also removed and the upper segment implanted into the bladder. Lymph nodes, macroscopically involved, were excised singly or in small groups. A perusal of the report reveals the wide variation in extent of resection among the patients described. In most instances a small cuff of vagina, not far beyond the tumor was resected. In other instances, most of the vagina was removed.

Booney was one of the staunch proponents of the surgical treatment for carcinoma of the cervix during the years when little else but irradiation was generally advocated. He referred to the operation performed by himself as Wertheim's operation and this contributed in no small measure to the establishment of this term at least in the English and American literature. Booney carried out a more radical procedure than originally described by Wertheim and emphasized systematic pelvic lymph node dissection in stages which the latter did not carry out. More recently in Meigs's writings on the sub-

ject, he refers to the radical hysterectomy with pelvic node dissection which he has developed as a Wertheim operation. Here again his procedures are more radical than those carried out by Wertheim and are more systematically extensive than can be witnessed in the Vienna gynecological clinics today and referred to there as Wertheim operations.

Many operators in carrying out some type of radical hysterectomy for cervix cancer likewise designate their procedures as Wertheims. The writer has witnessed operations, and observed the resulting surgical specimens which in fact were supravaginal panhysterectomies without systematic lymph node dissections and with relatively little pericervical tissue removed that were designated as Wertheim operations.

Obviously when the results of the surgical treatment of cervix cancer are discussed on the basis of

significant series of cases there will be a rather wide divergence in what has been achieved by the Wertheim operation. Under this heading will be grouped the stereotyped panhysterectomies that have been designated Wertheims, as well as the more radical procedures with systematic lymph node dissections.

It would appear, therefore, that there will be advantages in the substitution of the term Wertheim operation by more accurately descriptive terminology such as radical panhysterectomy" with or without limited pelvic lymph node dissection or with systematic iliac, hypogastric and obturator node excisions. Another designation might be radical panhysterectomy with *en bloc* pelvic node resection. With more accurate designations the achievements favorable and unfavorable of the operations might be more correctly evaluated.

ALEXANDER BRUNSWICHT.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

THE FORUM OF FUNDAMENTAL PROBLEMS FOR SURGICAL SPECIALISTS

HOWARD C. NAFFZIGER, M.D. F.A.C.S., San Francisco, California

At the annual Clinical Congress of the American College of Surgeons in the past several years, the Forum on Fundamental Surgical Problems has demonstrated its value and wide popularity. It was instituted to provide an opportunity for the young progressive researcher to present his work. Its appeal to such a large proportion of the members has been a source of great satisfaction to the College. Its value to the specialist was not fully appreciated at the beginning, but it is recognized now that a much needed opportunity is offered for specialists in all surgical branches to keep abreast of progress in the fundamentals.

Attendance at the Forum is huge and selection of this part of the program by such large audiences has a special significance. The specialists in fields other than general surgery have their own societies, meetings, and personal contacts often they have little time and little opportunity to learn of progress outside their own particular bailiwick. At such a Forum as this, the principles of management of infection, nutrition, improvements of anesthesia, the use of blood fractions and blood substitutes, and many other matters are presented. These are of immediate concern to each and every practitioner regardless of his specialty.

The Clinical Congress permits the specialist to renew acquaintance with fundamentals and to keep abreast of the broad advances which contribute to the welfare of all patients. The subsidiary trickles, continuously adding to the stream of medical knowledge, are increasing its volume and the speed of its flow, so that if we are not in it but

remain on the bank, we are promptly left behind. The language of the medical sciences must not become a foreign tongue when the days of our medical school teachings are past and the Forum offers an excellent opportunity as a refresher course.

The specialties are becoming more and more independent and autonomous. This is evident in the tendency toward their establishment as separate departments in our medical schools and by the creation of their own boards of certification and their own special societies. This development has its advantages and its drawbacks. It makes for progress in a narrowed field but inevitably tends toward separation from the broad base of Medicine. If this divergence proceeds too far the superstructure of specialism lacks a sound foundation. With this specialism which has reached its height in this country and with no signs of a tendency to abate, who is to contribute to progress in the fundamentals? So far progress has come largely from the preclinical and basic sciences. On the clinical side, the general surgeons are the particular ones who have contributed the most. Should we as specialists look to that particular specialty called General Surgery to carry on investigations and be responsible for the teaching of the basis of all surgery? It would seem that if the specialties and the specialists are to be worthy of their independence, their interest in broad fundamentals must not only be maintained, but they should contribute to knowledge in the fundamentals as well as in their own special precinct. This is the obligation that is assumed along with independence. The Forum, therefore, fills a special need for the specialist and it welcomes his attendance and his contributions.

COLLECTIVE REVIEW

ETIOLOGY OF ENDOMETRIOSIS

BROOKS RANNEY M.D. Chicago, Illinois

WHEN few facts are definitely known concerning the etiology of a condition, and when the interpretation of the known facts is not obvious, attempts are made to explain the observed phenomena by a workable theory. When all phenomena cannot be satisfactorily explained by one theory, the number of hypotheses purporting explanation multiplies, each being incomplete. When disproof of the various theories is even more difficult than their substantiation, these theories tend to creep insidiously into the minds of practical men as established fact—each man accepting most readily that idea which seems best to explain the phenomena he has observed. When theories concerning the etiology of a condition differ markedly and when the incidence of this condition seems to be increasing, much observation, investigation, and dissertation are thereby stimulated. Thus, in the extensive literature concerning the etiology of endometriosis, King (108) says, "one observes writers regarding the suggestion as fact—or at least intermingling observation and suggestion, so that the disentangling of description from hypothesis becomes extremely difficult. This discussion is an attempt to disentangle observation from suggestion and description from hypothesis concerning the cause of endometriosis."

DEFINITIONS

Novak (145) defines endometriosis as the condition in which tissue resembling endometrium more or less perfectly is found aberrantly in vari-

ous locations. Many authors differentiate anatomically between *internal* endometriosis (or adenomyosis) which is found extending diffusely through the myometrium, and *external* endometriosis which is found on or near the peritoneal surface of the uterus, ovaries, pelvis, or elsewhere in the body. When an isolated area of endometrial tissue, surrounded by fibrous or smooth muscle tissue, forms a discrete, individual tumor it is often called an endometrioma, or when located within the myometrium it may be called an adenomyoma.

The terms endosalpingiosis (occasionally found) and endocervicosis (rarely reported) are self-explanatory in the light of the foregoing explanations.

A detailed list of terms from several countries, which have been used to name various manifestations of endometriosis, has been compiled by Hosai (93).

CLASSIFICATION OF THEORIES

A consideration of the etiology of endometriosis must include evaluation of (I) the theories concerning histogenesis, and (II) those concerning possible stimulating influences. The theories concerning histogenesis may be divided into three general groups: (A) those which imply that ectopic endometrial tissue is transported from the uterus to its pathological location; (B) those which imply that ectopic endometrial tissue develops *in situ* from local tissues; and (C) combinations of these two groups. Theories postulating transport from the uterus may be named as follows: (1) the implantation theory, (2) the mechanical transplantation theory, and (3) the metastasis theory. Theories postulating development *in situ*

From the Department of Obstetrics and Gynecology at Northwestern University Medical School and Wesley Memorial Hospital.

may be named as follows: (1) the celomic metaplasia theory, (2) the ovarian metaplasia theory, (3) the dedifferentiation theory, (4) the embryonic cell rest theory, and (5) the direct extension theory. Of the many possible combination theories postulating both development *in situ* and transportation thence to final pathological sites, only one, which for lack of a better name is called the uterine endometriosis theory, will be discussed herein. Malignant changes will be considered briefly. Factors which may possibly stimulate the development of endometriosis will be discussed under three general headings: (A) mechanical, (B) inflammatory, and (C) hormonal.

HISTORY

The first known report concerning endometriosis was written by von Rokitanaky (165) who described an adenomyoma in 1860. Following this only a few scattered reports are available until the 1890's when a number of German and American investigators became interested in the subject. During the first two decades following 1900 studies of the subject were continued by these men—principally Cullen (24, 25, 26, 27) and Meyer (128, 129, 130, 131)—who published careful and extensive reports of their findings. However, Cattell and Swinton (19) were able to find less than twenty reports concerning endometriosis in the world literature prior to 1921.

In 1921 Sampson (174) published the first of his series of reports in which the implantation theory of endometriosis was recorded. These papers awakened wide interest in the subject of endometriosis in this country, and since that time the literature on this subject has expanded even out of proportion to the increasing frequency with which the disease is being observed.

A chronologically arranged history of the literature concerning endometriosis is tabulated in the appendix hereto.

I. THE HISTOGENESIS OF ENDOMETRIOSIS

Theories concerning the origin and method of development of endometriotic tissues will be discussed under this general heading:

A. ECTOPIC ENDOMETRIUM TRANSPORTED FROM THE UTERUS TO THE PATHOLOGICAL SITE

1. *Implantation theory* (following retrograde menstruation through the tubes) Sampson introduced this theory in the early 1920's, basing his ideas upon clinical observations and pathological studies (174). He first described "perforating hemorrhagic cysts of the ovary" and theorized that an abnormal corpus luteum may have de-

veloped due to invasion of endometrial tissue present at the site of rupture, and that "with the advance of the epithelial invasion the luteal membrane retrogresses to the extent that the mature cyst may be reined. (In this connection Kahanpaa reports the presence of endometrial glands and stroma in a *wonag corpora lutea*). Sampson stated, 'Usually there is a vascular stroma not unlike that of the endometrium between the epithelium and the ovarian tissue' and, 'structures like uterine glands may be present in this stroma.' Also in this first paper Sampson reported endometriosis in the cul-de-sac of patients who had only tiny pockets of endometrial-like epithelium in their ovaries, but who had much dense fibrous tissue around the ovaries. From this he concluded: (1) that endometrial cysts of the ovaries were sometimes lesions of relatively short duration, (2) that the characteristic adhesions resulting from their bursting and regression may persist long after the cyst has disappeared, and (3) that the material escaping from them may give rise to adenoma of endometrial type in other tissues. He called the lesions adenoma of endometrial type because: (1) they were histologically similar to endometrium, (2) they manifested activity (periodic hemorrhages) during the patient's menstrual life and (3) in some patients the ectopic endometrial tissue corresponded to the phase in the cycle indicated in the menstrual history."

During the next year Sampson (184) noted that various ovarian and peritoneal lesions of endometriosis seemed to be of the same age and histological structure in some individuals. Therefore he sought a common source for the endometrial tissue of these lesions. Naturally patent tubes were considered as possible avenues through which mullerian tissue might escape into the peritoneal cavity.

In 1922 Sampson (175, 176) presented his theory that bits of uterine and tubal epithelium were extruded from the fallopian tubes by retrograde flow during menstruation, and that they implanted, usually on the ovaries, but occasionally on the peritoneal surface of other pelvic structures, especially in convenient "pockets." This theory was based on several observations, namely: that endometriosis was seldom found in women under the age of 30, that both tubes were patent in 284 of the 293 patients which he studied (184), that endometrial hematomas usually developed on lateral and inferior surfaces of the ovary—the parts most likely to be soiled by material extruding from the tube—and that endometrial hematomas were often bilateral. To this, he

added another hypothesis, specifically that the ovary is an "intermediary host a hotbed or incubator of endometriosis" for the epithelium apparently expelled from the ovarian cysts seemed to him to be more vigorous in new implantation sites than the epithelium which seemed to have come directly from the tube to an extraovarian implantation site (175-176). (However while studying additional material (184) Sampson observed that extensive peritoneal endometriosis can occur without any ovarian involvement, and he finally concluded "Therefore the suggestion that the ovary may impart greater virulence to the Mullerian epithelium growing on it is unwarranted.")

These unusual theories naturally stimulated a great deal of interest and controversy. King (108) studied the same type of ovarian lesions as did Sampson, but derived therefrom a different interpretation which will be discussed later. Ewing and Novak (142) pointed out that endometrial islands are usually found deeper within the tissues than would be expected of surface implantations. Novak also pointed out that typical endometriosis is found in the umbilicus where implantation is improbable. However Campbell dissected the umbilical area of patients who had umbilical endometriosis, and was able to satisfy himself that the long tracts of scar tissue he found were the remains of small hernial canals into which endometrial tissue might have implanted after extrusion from the tubes. On the other hand Enzer observed a dimpling on the peritoneal surface of an umbilical endometrioma removed from an 18 year old girl. The invaginated area was serially sectioned but no evidence of implantation was found. "The lining epithelium resembled by periplastic peritoneal cells. (See celomic metaplasia theory.)"

Hirst reported the case of a 19 year old girl who for 3 years prior to operation, had menstruated into her peritoneal cavity with much associated pain. The operative findings included a rudimentary blind vagina a solid cervix widely patent tubes, normal ovaries containing a fresh corpus luteum but no endometriosis or adhesions.

This patient should have been an ideal subject, for the development of endometriosis according to the retrograde menstruation theory. However Yin reported the case of a 19 year old girl who for 2 years prior to operation had menstruated painfully into her peritoneal cavity. The operative findings included an atresia of the lower vagina, a uterine lumen dilated with tarry blood and endometriosis of the bladder wall intestines, omentum tubes, and right ovary. In these 2

cases similar anomalies interfered with normal vaginal menstrual flow, yet one patient developed endometriosis and the other did not. Apparently some factor other than or in conjunction with retrograde menstruation is necessary for the development of endometriosis. (See mechanical factors.)

The discussion thus far has dealt with large elements of theory laced together by clinical and pathological observations. Let us consider what other facts are available.

Autotransplantation of endometrial tissue into the liver spleen abdominal wall, and/or anterior chamber of the eye has been successfully accomplished in smaller experimental animals, first by Goldzieher in 1874 then by Stilling in 1910 and later by Hesselberg *et al.* Jacobson (98-99) Spirito Allen and Bauer Gleave, Harbitz, Kirchsky and others. Stilling observed that adenomas of various sizes were formed which were lined with ciliated columnar epithelium and which contained fluid under pressure. Cyst walls would regenerate after excision of a portion for microscopic section. Kirchsky noted that the vascular changes of an intraocular endometrial transplant in pregnant rabbits corresponded with the changes within the uterine endometrium. Spirito reported success in transplanting endometrium either to the same animal or to an animal of the same sex and species, but no success has been reported in attempts to transplant endometrium to animals of different species.

Jacobson (100, 101) Fraser and Markee have transplanted healthy nonmenstrual endometrium in monkeys. Jacobson found successful transplants were confined to the uterine serosa and adhesions. However Fraser reported takes in the serosa of the bowel and umbilicus and Markee was very successful with implants into the anterior chamber of the eye. Thus, healthy surgically transplanted nonmenstrual endometrial tissue will usually survive, flourish and respond to those hormones which normally effect intrauterine endometrium.

Heim (80-81) Traut, Caffier Hirsch and Jones, and Katz and Szenes succeeded in culturing endometrium taken from surgically removed uteri which were not in the menstrual stage. Traut found that this healthy endometrium grew best in a culture of corpus luteum hormone, grew fairly well in embryonic extract, but died within 6 days in a culture of ovarian follicular fluid.

However Novak and TeLande (146) stated that menstrual discharge tissue is necrotic, containing chiefly autolyzed constituents with few if any formed elements during the first 2 days of the

menstrual flow and no demonstrable endometrial tissue after the first 2 days. It was considered reasonably doubtful that such sloughed endometrial tissue would retain sufficient viability to implant itself survive, and flourish. Meyer (133) wrote that if the viability of menstrually discharged endometrial particles could be definitely proved, the first question concerning the implantation theory would be answered.

To study the viability of endometrial particles during menstruation, Cron and Gey obtained small bits of tissue from the human uterus on the second day of menstruation with a dull curette and were able to keep the tissues alive for a month in cultures. Some glandular hyperplasia was observed but the explants did not become grossly larger. However by using a curette they may have obtained tissue from the deeper portion of the endometrium which normally would not have sloughed during menstruation, and which may logically be expected to show greater viability than would menstrual particles obtained without instrumentation. Therefore, Geist collected human menstrual blood in a test tube at the cervix. It had been argued that menstrual particles small enough to pass through the interstitial portion of the fallopian tube would be necrotic so Geist aspirated some menstrual blood from the test tube through a capillary pipette which he considered to be approximately one-third the diameter of the average interstitial tubal lumen. He then placed the aspirated material on a slide where he stained it supravitality. He interpreted his findings to mean that endometrial cells are living and remain alive for at least an hour after they escape from the cervix. This, however is not proof that the cells would have sufficient viability to implant and live on ovarian or peritoneal surfaces.

Craig has summarized the observations of various investigators of this subject as follows: "Tissue culture experiments on the viability of endometrium have shown that postmenstrual endometrium grows easily and rapidly. Interval endometrium also is grown without difficulty. Premenstrual endometrium is more difficult, but endometrium obtained during menstruation is scarcely viable and extremely difficult to grow."

The question then arises: Is there a sufficient degree of viability to sustain endometrial particles until implantation can occur? In an attempt to answer this question Heim (82) implanted desquamating menstrual mucosa from either monkeys or human beings into the peritoneal cavities of monkeys. In no instance was he able to find any takes. He was also unable to produce pelvic endometriosis in monkeys by creation of utero-

abdominal fistulas which permitted leakage of menstrual blood into the pelvis. Hartman reported the histories of 2 monkeys. The first, when received from the shippers in the jungle, was found to have a complete, spontaneous or traumatic separation between the cervix and the body of the uterus. The cavity of the uterus contained bits of bone and sludge. The connection between the uterus and cervix of the second animal was surgically severed by TeLinde, and some months later an exploratory laparotomy was performed. Neither animal had any blood or endometriosis in the pelvis or abdomen. Thus, available experimental evidence indicates that menstrually discharged endometrial particles lack sufficient viability to implant and grow in a manner comparable with intermenstrual endometrial particles.

In some of the experiments herein reported the viability of endometrial particles passing out of the cervix was assumed to be the same as the viability of endometrial particles which might pass out of the fimbriated end of the tube. This assumption has never been checked directly; however Sampson (180) compared the microscopic appearance of uterine mucosae (1) obtained at curettage, (2) obtained from vaginal menstrual blood, and (3) obtained from a cast of the tube. He found what he interpreted to be healthy cells and cell groups in all 3 types of specimens. Westons (214) examined blood taken from the cul-de-sac of patients who were operated upon at the time of menstruation. He observed red blood cells, leucocytes, endometrial cells, and clumps of amorphous debris therein. Thus, endometrial type cells which may have traversed the fallopian tube in a retrograde direction have been recognizable microscopically. However it is pertinent to mention that loss of physiological function would precede structural change so that histological structure is not an exact criteria of cellular viability.

In 1925 Rubin (166, 167) and Lee (114, 115) studied the physiology and anatomy of fallopian tubes—Rubin studying human beings and Lee studying dogs, cats, and guinea pigs. Both concluded that uterotubal insufflation is most difficult at the time of menstruation, or its equivalent (from 180 to 200 mm. Hg. pressure being required in human beings). Just after menstruation ceases the pressure necessary for insufflation usually is only about 70 mm. Hg. in human beings, and it remains at this point until about the time of ovulation when it starts to rise again. Lee discovered that the uterotubal junction was guarded in all observed animals by fibromuscular folds—which were grossly viable in the pig. Neither he nor

Rubin could see such a structure in the human uterus, but one of Rubin's uterosalpingograms (167) shows possible evidence of such a "sphincter" between the uterine cornu and the interstitial tube. From his studies, Rubin concluded that spasm of the tube is rare (occurring in 9 of 450 cases) but that in the presence of a foreign body in the tube peristalsis toward the uterus takes place. He also states that reverse peristalsis may occur occasionally (168) and if so this would favor retrograde menstruation.

Finally Markee in elaborate and painstaking experiments, transplanted endometrium under sterile precautions, to the anterior chamber of the eyes in 41 monkeys. Using high magnification he made daily observations of the changes within the endometrial transplants during 432 estrus cycles. Among his observations concerning menstruation he mentions the following:

1. Menstruation is preceded from 2 to 6 days by a decreased blood flow to the mucosa.
2. There is a marked vasoconstriction from 4 to 24 hours before menstruation begins.
3. Shedding of the fragments starts a day after the beginning of menstrual bleeding.
4. Fragments usually disintegrate and disappear within from 30 to 60 minutes after they are shed.

5. In not a single instance during the entire 432 cycles did reimplantation of a shed fragment occur although the original implants of healthy endometrial tissue had established themselves with ease in every instance in which infection did not supervene.

This is the only experiment in which the course of endometrial fragments which were shed during menstruation onto a favorable implantation site has been observed in vivo and reported. The uniform absence of secondary implantation and the rapid disintegration of shed fragments are definite although not incontrovertible, evidence against menstrual regurgitation as the usual etiologic agent in the production of pelvic endometriosis.

2. *Mechanical transplantation theory* Transplantation into laparotomy scar. In 1916 von Franke first suggested that laparotomy scar endometriosis may result from surgical transplantation of endometrial tissue. He reported a case of scar endometriosis following repair of a uterus which ruptured early in pregnancy. Danforth (33) and Heaney in 1925. Nicholson in 1926 and others (5, 54, 75, 78, 94, 182, 185) have reported instances of endometriomas of the laparotomy scar following surgery in the pelvic region. In 1949, Wepi and Kletzhandler reported that during the preceding 16 years they had removed 73

scar endometriomas, 5 following cesarean section and 68 following hysterotomy. They also reported that, since changing their surgical techniques, their incidence of postoperative scar endometriosis following these operations had dropped from 3.4 per cent during the early years of the report to 0.9 per cent during recent years. In his comments on this report Greenhill in 1942 stated that the previous world literature had contained only 390 cases of scar endometriosis, which he classified roughly as follows:

REPORTED POSTOPERATIVE SCAR ENDOMETRIOMAS

Operation	Number
Ventrofixation	113
Cesarean section	41
Hysterotomy	49
Other openings made in uterus	26
Adrenal operations	51
Appendectomy	18
Vulvar vaginal perineal scars	43
All others	49
Total	390

Sampson's studies (181, 182, 185) have made it apparent that, if records were adequate for the purpose, these scar endometriomas should really be separated into two groups: (1) those which developed by direct extension (see direct extension theory) and (2) those which developed following actual transplant of endometrial tissue.

Hosal and Meeker (94) and Pankow mention instances in which scar endometriomas were discovered as long as 26 years after childhood appendectomies. Sampson theorizes that such lesions develop from bits of an endosalpinx transferred from the tube to the wound on gloves or gauze by the exploring surgeon.

There is no doubt that endometrial tissue can be transplanted during surgical procedures either accidentally or intentionally. Hasselberg *et al* successfully transplanted uterine tissue into abdominal muscles and into ear tissue in guinea pigs. Bykow successfully transplanted the entire uterus of immature dogs to the omentum. Both investigators observed little if any tendency toward proliferation of the transplanted myometrium. Bykow stated that only the endometrium exposed by amputation showed a tendency toward active proliferation. In this connection Jacobson (99) made a simple incision in pregnant uterus of rabbits and was later able to demonstrate endometrial cysts in the region of the incision. Harbitz transplanted endometrium into peritoneal and pleural cavities. These transplants became rapidly cystic, acting in that respect similar to other transplanted epithelia.

(skin, mucosa of mouth, ureter [225]) The pleural transplants became rapidly extrapleural, cystic, and then polypoid.

Transplantation into lower genital canal. As previously stated, Greenhill recorded 43 instances from the world literature, in which vaginal, vulval, or perineal scars contained endometriomas. Hosal (93) mentions instances of menstruating fistulous tracts in the vaults of vagina following complete hysterectomies. Lash and Rappaport (113) in 1943 found only 5 cases of primary cervical endometriosis in the literature and added a sixth of theirs. In each of these 6 cases a traumatic lesion of the cervix from abortion, curettage, or childbirth had preceded the onset of symptoms by several years. Thus, there is some evidence that endometriosis of the lower genital tract may result from mechanical transplantation.

Transplantation to pelvic organs following curettage. The evidence for this possibility may be stated as follows:

1. In 1925 Rubin (166) condemned the use of uterine irrigations following curettage because at subsequent laparotomies he had frequently seen the pelvis inundated with fluid which had washed through the tubes.

2. In 1927 Sampson (180) reported that at laparotomy following curettage, he frequently observed blood from the uterus escaping through the tubes into the pelvis.

3. In 1944 Hartman did a series of experimental hysterectomies on monkeys during which he attempted, by excision and vigorous wiping to remove all vestiges of endometrium from the uterus. Not only did the intrauterine endometrium regenerate completely in from 14 to 30 days, but there were numerous takes of spilled endometrial fragments on the external surface of the uterus, some producing "chocolate cysts," and nearly all, when studied, showing cyclic activity parallel to that within the uterus.

4. In 1946 Curtis (31) recorded 2 similar instances which had been brought to his attention. Both patients had laparotomies at which incidentally no endometriosis was noted. Later both were subjected to dilatation and curettage, followed immediately by Rubin tests. Some time after this, both required laparotomies for the treatment of pelvic endometriosis.

5. It should be repeated here that Rubin (168) has occasionally observed what appeared to be reverse tubal peristalsis under the fluoroscope when opaque material was in the genital canal.

Thus, there is no proof but only suggestive evidence that bits of healthy endometrium broken off by a curette may flow or be forced out of the

tube with blood and may implant on the surrounding peritoneal surfaces.

3. *Metastasis theory* Lymphatic metastasis. In 1924, Halban (72) first recorded his belief that the presence of endometrial like tissue found deep beneath apparently normal peritoneum was not explainable upon the basis of any prevailing theories, but was explainable only on the basis of spread through the lymphatics which drain the uterus. A year later Halban (73) reported 5 cases of endometriosis in which he attempted to show that the lesions were distributed along the course of the lymphatics. He also referred to uterine mucosa found in inguinal, sacral, iliac, and parametrial lymph nodes of women by Ries, Wertheim, Meyer, Frankl, and Lahn, and stated that no such tissue had been found in similarly located glands in men.

In 1925 Sampson (177) could not rule out the possibility of lymphatic metastasis in the etiology of inguinal endometriosis. Later while studying endosalpingiosis (182) he injected dyed gelatin under moderate pressure into the uterine lumen before he cut tissue blocks. In one section he demonstrated a gelatin filled, endometrial gland growing within the lumen of a lymph vessel in the tubal wall. This could be interpreted only as evidence that endometrial tissue may travel, at least by extension, through lymph vessels. (It has been suggested that such extension through lymphatics is the usual mode of development of adenomyosis (58). In the rare condition known as stromal endometriosis, extension of endometrial stroma through the lymphatics is usually observed.)

Hansmann and Schenken reported the autopsy findings in 2 young women. One died of a transfusion reaction but had chorioepithelioma. The other died of gunshot wounds, but had ovarian endometriosis. Therefore, the pelvic lymph nodes were sectioned and in both instances glandular cysts lined with ciliated, columnar epithelium and surrounded with endometrial stroma-like tissue were found within the nodes. Russell (169) found multiple small glands lined by columnar epithelium and surrounded by decidual cells in the cortex of an abdominal lymph node of a young woman who died of hemorrhage following rupture of an ectopic pregnancy.

Whether these glandular and stromal findings within lymph nodes are due to metastasis of endometrial cells, or are due to metaplasia of the lymphatic endothelial and stromal cells (83, 180) is not known. Sternberg and Carere-Comes have reported decidual reactions in axillary parotid, and submaxillary lymph nodes. An ectopic decidual reaction does not necessarily indicate that

ectopic endometrium is present. However it does show a predisposition of the local tissue to respond to hormonal stimuli in a manner similar to endometrial stroma by the development of decidual like cells (144).

Thus, the evidence for lymphatic metastasis is incomplete. Further studies of this subject will likely emanate from the autopsy room.

Venous metastasis. As early as 1925 Sampson (177) suggested the possibility that endometrial particles might get into venous sinuses and be carried thence to an abnormal location there to implant and grow. In 1936 Navratil and Kramer (138) reported the removal of a date sized fibrotic mass of endometriosis from the external carpi radialis muscle of the arm of a 25 year old girl who had a previous therapeutic abortion. Three years after excision of the arm lesion she was suffering severe symptoms of dysmenorrhea and menorrhagia and Navratil (137) removed her uterus. The uterus showed generalized adenomyosis.

By 1939 Philipp and Huber (154) reported that there were 3 known instances of endometriosis of an extremity and since then there have been others—the most recent being the report by Schlicke, in 1946 of a nodule removed from the posterior aspect of the thigh of a Filipino nurse. For 3 years prior to the operation this nodule had become larger and more tender just before and during menstruation, and had regressed in size and tenderness during the interval between.

If endometriosis of an extremity is to be considered as evidence for venous metastasis of endometrial particles, one of the following two assumptions must be made (1) either a patent foramen ovale or similar defect existed in the cardiovascular system and shunted blood past the pulmonary vascular system, or (2) an initial endometriosis existed in the lungs and metastasized to the extremity. Neither has been reported. However another histogenetic explanation for the existence of endometriosis of the extremities will be discussed later (see celomic metaplasia theory).

Schwarz reported the case of a woman who had inguinal endometriosis, and who had definite epistaxis with each menstrual period until she was subjected to x ray castration. However after a meticulous study of rhythmic changes in the skin capillaries, Brewer pointed out that menstruation which is evidenced as a local vascular phenomenon is in reality a part of a demonstrable generalized vascular phenomenon present in the entire body. In light of this conclusion the reported epistaxis could be explained more logically as bleeding evoked by these generalized vascular

phenomena, from any one of several common pulmonary lesions rather than from a hypothetical pulmonary endometroma.

Experimental endometriosis of the lungs was produced in rabbits, by Jacobson (102) in 1932 and by Hobbs and Bortnick (88 89) in 1939. Bits of autogenous endometrium were injected into the rabbits ear veins in saline suspension or in autogenous serum suspension. Jacobson found apparently viable, embolic cells in the lung up to 1 week after injection, but no longer. No cells passed through the lungs to other organs. Hobbs and Bortnick gave their rabbits theelin in oil preoperatively to stimulate endometrial growth. They were able to find endometrial implants in the lungs of 8 of 12 rabbits.

Thus, the evidence for venous metastasis is incomplete. It seems likely that if healthy endometrial particles were present in the venous blood from the uterus they would be filtered out and implanted in the lung rather than elsewhere.

B ECTOPIC ENDOMETRIUM DEVELOPED IN SITU FROM LOCAL CELLS

1 *Celomic metaplasia theory* This theory of the origin of endometriosis has evolved gradually as the result of observations, experiments, and writings of many men principally Waldeyer Iwanoff Meyer (131) Novak (143) Heim (83) and Gruenwald (67 68 69 70 71). In its present form simply stated, it is this: the muellerian (paramesonephric) duct is derived from the embryonic celomic epithelium and mesenchyme, and forms most of the female genital tract including the endometrium. Other adult derivatives of these embryonic celomic cells may retain the potentiality of forming tissue which is histologically and functionally indistinguishable from endometrial tissue.

To evaluate the celomic metaplasia theory it is first necessary to consider the most recent fundamental embryological studies which have a bearing thereon. These have been reported by Gruenwald (67 68 69 70, 71).

Early in embryonic development the cells lining the celomic cavity have a characteristic appearance. As Maximow reported, in 1927 the celomic surface of these cells forms a smooth lining for the celomic cavity. However the basal border is irregular. There is no basement membrane. The lining cells send cell processes into the mesenchyme and continually "bud-off" cells into it, thus giving rise to part of the mesenchymal tissue (Fig 1).

Soon, however in the human embryo of 8 mm the celomic lining differentiates into true epitheli-

Fig. 1. Lining of celomic cavity—early. Cell surfaces lining the celomic cavity are rather smooth (a), but then opposite surfaces are irregular and there is no basement membrane (b). Lining cells send cell processes (c) into the mesenchyme and continually “bud-off” cells (d) to it, thus contributing to mesenchymal cell content (e). (Adapted from Gruenwald [7].)

Fig. 2. C-ionic epithelium (8 mm. human embryo). The celomic lining differentiates into true epithelium (a) at basement membrane (b). It no longer contributes cells to the mesenchymal tissue (a). (Adapted from Gruenwald [7].)

um with a basement membrane, and it no longer contributes to the mesenchymal tissue (Fig. 2).

The third phase in the embryonic history of the celomic lining was described by Filatow (45) in 1933. A blastema is formed by the following process:

At specific places the celomic lining epithelium dedifferentiates to its original condition, sending cell processes into the mesenchyme and budding off cells. Such blastema forms the primordium for the gonads and limb buds (Fig. 3). (At the time of formation, portions of some of the blastema are in the embryo's future thoracic region, i.e., the upper end of the gonad and the cephalad limb bud.) The organs thus produced inherit and under normal conditions, repeatedly demonstrate a greater tendency than other bodily tissues toward interchanges between epithelial and mesenchymal structure.

Gruenwald put these facts together and then went on to study the development of muellerian (paramesonephric) ducts (67, 68). He observed, as had his predecessors, that the paramesonephric duct originates by an invagination of celomic epithelium near the cephalad end of the wolffian (mesonephric) duct, and of the gonad, and grows caudally just under the coincidentally developing tubal ridge, which is a thickening of the celomic epithelium. He discovered that the two ducts are at first clearly separated only at the moment of invagination, and that thereafter the paramesonephric duct grows caudally within the basement membrane of the mesonephric duct. He also discovered that epithelium of the paramesonephric duct buds off mesenchymal cells on its dorsal and lateral surfaces, which separate the paramesonephric and mesonephric ducts. Up to

this time, he observed that the ventral surface of the paramesonephric duct usually rests directly on the basement membrane of the thick tubal ridge. However, the tubal ridge epithelium now buds off mesenchymal cells which separate it from the paramesonephric duct. All these mesenchymal derivatives of epithelium rapidly become histologically indistinguishable from the surrounding mesenchyme (Fig. 4).

These facts are beautifully illustrated in high power photomicrographs of specially stained sections of human and chick embryos in Gruenwald's several publications. They may be presented in diagram form (Fig. 5).

The implications with reference to endometriosis are summarized neatly by Gruenwald (69), as follows:

1. The celomic wall, including epithelium and connective tissue, is developmentally related (progenitor) to the muellerian (paramesonephric) ducts, and therefore may be regarded as a possible bearer of the developmental potentialities of endometrium formation.

2. This potentiality may be carried into other organs which develop from blastema derived from the celomic wall, i.e., the gonads, adrenals, and limbs.

3. Nonepithelial tissues of the uterus are particularly closely related to uterine epithelium, since they are formed by that epithelium during embryonic life.

4. Spontaneous endometriosis in all known locations may originate from local tissues.

More specifically, cells which are descendants of the celomic epithelium, and which therefore may retain the potentiality of endometrium formation, are present in large numbers in the upper genital organs and the pelvic peritoneum, but also are present, perhaps to a lesser degree, in the following listed locations in which endometriomas have been occasionally reported:

Fig. 3. Blastema formation. The colonic lining epithelium differentiates at specific places, sending cell processes (c) into the mesenchyme and budding off cells (d) to form blastema (a) which are the primordia for gonads, and limb buds. The surrounding epithelium (f) and mesenchyme (b) retain their normal cell structure, separated by a basement membrane (e). (Adapted from Gruenwald [71])

Fig. 4. Development of a paramesonephric duct (diagrammatically represented by a sagittal section above with corresponding cross sections beneath). Since the paramesonephric duct originates by invagination of the colonic epithelium (a) near the cephalad end of the gonad, and grows caudally within the basement membrane of the mesonephric duct just under the coincidentally developing tubal ridge (c) early stages of paramesonephric duct development can be shown in one diagram. Soon the epithelial cells of the paramesonephric duct bud off mesenchymal cells (heavy dots) dorsally (d, e) and laterally (e, f) which separate it from the mesonephric duct. Then the tubal ridge epithelium buds off mesenchymal cells (g, h) which separate it from the paramesonephric duct. Thus, the mesenchyme surrounding the paramesonephric duct (h) is derived from the ductal and tubal ridge epithelia, both of which were previously derived from the colonic lining epithelium. (Adapted from Gruenwald [72])

Extremities upper (137-138) lower (190)
Vagina upper two-thirds (134)
Pleura (12)
Peritoneum, other than pelvic umbilicus (38, 108, 216) inguinal (27) serosal surface of ureters (37, 147) serosal surface of bladder wall (106, 116, 147)
Lymphatic endothelium in pelvic region (189)

Walker Taussig and Weller (219) have reported that decidual reactions can occur in the tissues immediately beneath the peritoneal mesothelium. This, of course, cannot be taken as proof that these tissues can change into endometrial stroma. Rather it is indicative that these tissues have retained a sensitivity to a hormonal factor similar to that which produces a decidual reaction in the endometrial stroma. This is reasonable since both peritoneal subserosa and endometrial stroma contain many cells which are descendants of the embryonic colonic lining. With this common ancestry in mind, Weller (219) credits Schiffman and Seyfert as the first to observe a similarity between frequent locations of decidual reactions and frequent locations of endometriosis.

In 1932 Sampson (183) expanded his theories sufficiently to report that cases of 'Primary Fimbrial Endometriosis' develop from the activation and differentiation of the tubal mucosa of the fimbriae into a structure resembling endometrium.

Microscopical examination of an umbilical endometrioma from an 18 year old girl was reported by Enzer. He found that the peritoneum over the tumor was composed of hyperplastic, columnar cells which dipped down toward the tumor. He also found a glands containing cells which seemed to be more tubal than endometrial in appearance.

Others (39, 148, 181) have reported the observation of glands of the tubal type epithelium side by side with glands of endometrial type of epithelium in sections of endometriosis. Likewise, various stages of development or 'maturity' of epithelium, stroma and/or gland may be observed in a single microscopic section of endometriosis, which lends credence to the metaplasia theory.

After studying the replacement of desquamated uterine epithelium in the guinea pig in 1933, Papanicolaou reported that the new epithelium forms from undifferentiated cells of the stroma just beneath. These become epithelial in character and proliferate until they completely line the

Fig. 5

denuded surface. However he attempted no corollary explanation of the regeneration of human endometrium or the formation of adenomyosis. DeSnoo went one step further into theory. He stated that the endometrium regenerated during the postpartum period and following menstruation by differentiation of undifferentiated cells which he termed *genioblasts*. He also believes that the same type of cells, ectopically located, produce endometriosis if adequately stimulated, as they are stimulated in the endometrium by hormones.

The celomic metaplasia theory permits a physiological explanation, based on embryological as well as pathological observations, for spontaneously occurring endometriosis in any portion of the body in which it has yet been reported. Therefore, it is particularly appealing to many investigators as the primary explanation for endometriosis. Unfortunately conclusive proof of the validity of this theory is now and possibly always will be, lacking.

2 *Ovarian metaplasia theory* This is a first cousin of the theory just discussed. King (108) was impressed with Sampson's early reports (174, 175, 176) concerning hemorrhagic cysts of the ovary so he made a thorough study of these lesions. By 1933, he had developed his own interpretation which may be stated as follows:

Endometrium-like hemorrhagic cysts of the ovary result from changes in cystic atretic follicles and cystic corpora lutea. His evidence for this was (1) that in the resolution of atretic follicles and corpora luteum cysts one observes hemorrhage, luteinization of parts, hyalinization of parts, and the presence of macrophages, and all these changes are evident in "endometrial-like" cysts of the ovary (2) that the epithelium found in these endometrial cysts varies from flat through cuboidal to columnar and that the cysts are usually only partially lined with epithelium, and (3) that the stroma found around the cysts varies from almost none to an abundant collection around the cysts or glandlike projections from the cysts. King then states that the implantation theory of origin of endometrial tissue in these cysts ignores the afore mentioned microscopical findings, and adds, as inferential evidence for the ovarian metaplasia theory that the absolute sterility commonly associated with endometriosis of the ovary variously reported (19, 41, 77, 107, 118) as from 20 to 70 per cent, suggests primary ovarian malfunction. Cordus had somewhat similar ideas. He interpreted his sections to show that the endometrioid epithelium was derived from either germinal epithelium or granulosa cells.

Allen (3) and Keeno and Kimbrough (107) reported that ovarian endometriosis occurred much more frequently than did endometriosis elsewhere outside the uterus in their respective series of operative patients. However Pemberton makes a point of the fact that ovaries are not involved in 13 per cent of cases. Bloom states that "the cells of ovarian stroma are probably not common fibroblasts, for they may give rise to interstitial cells and, in ovarian pregnancy to decidual cells. Scott stated the opinion that, as the distance from the ovary increases, the tendency of subperitoneal tissues to produce decidual reaction (when properly stimulated) decreases. Thus, ovarian tissue and neighboring tissues seem to be more susceptible to stimulation by the sex hormones than other tissues outside the uterus.

Novak (143) while rebutting the theory of menstrual regurgitation of endometrium, offered the opinion that in those occasional instances when endometrial particles are found within the lumina of tubes they have come from ovarian endometriosis, rather than vice versa, because of the normal direction of flow within the tubes.

Unfortunately all of these reports and studies are open to wide variance of interpretation so that proof or disproof of this theory is impossible at present. The solution of this problem awaits for their extensive microscopic study of ovarian pathology and related lesions in the pelvis.

3. *Dedifferentiation theory* This is a second cousin of the celomic metaplasia theory. Bruce and Blain, while studying the incidence of adenomyosis in a large series of uteri, stained sections with Heidenhain's modification of Mallory's aniline blue stain. They were impressed, first, with the similarity of staining qualities of the interstitial (or stromal) cells of the endometrium and the muscle cells of the myometrium. Second, they noted differences in density of the true reticular stroma, which was dense and compact in the myometrium, but fine and delicate in the endometrial tissue—whether regular or ectopic. They noted a zone of gradual transition between myometrial and endometrial cells and stated that it was impossible to determine whether the cells in this zone belonged to one or the other group. They stated that the cells of the myometrium and those of the endometrial stroma are genetically related. In 1943 they postulated that myometrial cells may undergo a process of dedifferentiation into less mature cells which possess the potentiality (1) of forming the interstitial cells of endometrial stroma, and (2) of differentiating into epithelial cells to form glands within that stroma.

Concerning the latter half of this postulate Papanicolaou demonstrated heteroplasia from stromal to epithelial cells in the endometria of guinea pigs. Also Frankl states that stromal cells are found first in endometriogenetic islands during the development of internal endometriosis, and that glands appear later—the epithelial tissue of which he describes as heterotopic.

This is an interesting theory feasible on an embryological basis but extremely difficult to prove. Theories relevant to the development of adenomyosis are discussed in the section entitled *direct extension theory*.

4. *Embryonic cell rest theory* The pelvis occasionally contains bits of abnormally placed tissue (40). Some of the earliest theories concerning the cause of endometriosis dealt with the possibility that embryonic cell rests of paramesonephric or mesonephric tissue might grow during adult life.

Paramesonephric (Muellerian) Russell (170 171) in 1888 was the first proponent of the paramesonephric cell rest theory concerning the origin of endometriosis. Ahumada and Sammartino in 1942 utilized this theory to explain the occurrence of endometriosis in the perineum. More recently Gold and Kearns reported several instances of localized macroscopic, cystic adenomyosis. They classified these as rare, but worthy of note because they considered the most likely explanation for such lesions to be that remnants of paramesonephric duct tissue had been misplaced during embryonic development.

McDonald reported a congenital anomaly of the female genital tract in a young adult. The patient had a uterus didelphys in which the left uterus, tube, and ovary were normal. However the lower end of the right uterus was not connected to the cervix or vagina, and just at the place where the connection of the lumina should have occurred there was endometriosis under the pelvic peritoneum. The most logical theory of origin for this endometriosis, in view of the associated lack of fusion of the embryonic paramesonephric ducts, would be the paramesonephric cell rest theory. However existence of thickened columnar celled serosa over the endometriosis suggested the celomic metaplasia theory of origin. The existence of multiple follicular and corpus luteum cysts (one being hemorrhagic) in the right ovary suggested the ovarian metaplasia theory of origin and the existence of a moderate hematometra suggested the possibility of the implantation theory of origin. Here in a single case, are exemplified some of the difficulties encountered in attempting to evaluate the origin of endometriosis from clinical evidence.

The most rational argument against the paramesonephric cell rest theory of endometriosis is that if paramesonephric cell rests were present, and were susceptible to stimulation by ovarian hormones in the same manner as the endometrium one would expect the most frequent occurrence of symptomatic endometriosis thereby developed in girls of late teen age or in the early twenties (early sexual life) because of ectopic menstruation. However endometriosis actually is observed most frequently in mature women of the late thirties and early forties (late sexual life) (19 41 107).

Actual proof or disproof of this theory is not possible at the present time.

Mesonephric (Wolffian) Von Recklinghausen (161, 162) in 1895 (with reference to uterine adenomyomas) and Pick (158) in 1896 (with reference to ovarian endometriosis) were the first proponents of the theory that endometriosis originates from mesonephric cell rests. Residual tissue from mesonephric ducts occasionally produces cysts or adenomas in the lateral wall of the vagina or cervix or in the broad ligament. However there is no evidence that this tissue will undergo changes which cause it to become endometrial in appearance. Probably because of the known differences in embryonic development of the mesonephric and paramesonephric ducts the mesonephric cell rest theory has not been utilized in recent years to explain endometriosis.

5. *Direct extension theory* This theory applies especially to the development of adenomyosis (internal endometriosis) but also has been applied to some instances of endometriosis in which the ectopic tissue has spread beyond the confines of the uterus (external endometriosis).

Cullen (25) demonstrated in 55 of 56 adenomyomatous uteri that the gland elements of the ectopic tissue were derived from and usually were a direct continuation of uterine endometrium. The reason why such stromatous and glandular extension is possible has been best expressed by Bloom. While discussing the histology of the female genital tract, he states, "No true muscularis mucosae and therefore no submucous layer can be distinguished. The mucous membrane is immediately surrounded by a muscular coat. Apparently the extending endometrial tissue takes the line of least resistance whether it be between muscle bundles (Cullen 28) or through lymph channels (Sampson, 181). However Meyer (132) has called attention to the destructive action of islets of endometrial stroma on myometrium with the implication that this action facilitates the extension of stroma through myometrium.

Normally there is some dipping down of the basal endometrium into the irregular inner surface of the myometrium. Any dividing line between supposedly normal, and apparently abnormal extension of endometrial tissue into the myometrium is a purely arbitrary one based on individual experience. What causes internal endometriosis to develop in some women and not in others is not known, but one theory will be discussed later (see mechanical stimulating factors).

Direct extension of endometrial tissue into the myometrium has been thoroughly studied (15, 26, 27, 28, 119) and is generally considered to be the most frequent mode of development of internal endometriosis. Sampson (181) has shown that endometrial glands may extend well beyond the confines of the uterine wall and yet maintain lumina which are continuous with the lumen of the uterus, thus producing internal and external endometriosis.

Endometriosis is rarely reported in the cervix (90). Danforth (31) has demonstrated that the cervical wall is composed primarily of tightly interwoven fibrous tissue, differing in this respect from the more loosely arranged bundles of muscle tissue which compose the uterine wall. Since extension through fibrous tissue would be more difficult than extension between muscle bundles, this anatomical difference may explain the rarity of cervical endometriosis.

A descriptive sentence concerning endocervicitis should be inserted here. This condition occurs rarely. As described by von Törzsay Kiss (206) it consists of epithelial glands of cervical type extending deeply into the fibrous tissue of the cervix. It does not respond cyclically to ovarian hormones in the manner of the endometrium, but only secretes mucus.

C. ECTOPIC ENDOMETRIUM EXTENDING FROM TISSUES OF ORIGIN THENCE TRANSPLANTED FROM SITE OF EXTENSION—COMBINATION THEORY

1. *Uterotubal endometriosis theory* In 1903 Meyer (128) wrote an article entitled "A hitherto unknown type of adenomyoma of the uterus, in which he described an instance of endometriosis in a laparotomy scar following an operation for salpingectomy and ventrofixation. In the 1920's Sampson (181, 182, 185) studied a series of similar postsalpingectomy adenomyomatous lesions of abdominal scars which he named "postsalpingectomy endosalpingiosis. He found this proliferation of endosalpingian intramural glands in 112 of 147 of the tubal stumps (75%). He also found endosalpingiosis (tubal adenomyosis) in 16 of 200 tubes not operated on (8%) Sampson (185)

also studied the pathogenesis in 17 instances of laparotomy scar endometriosis, all but one of which followed salpingectomy. In 12 of these he injected dyed gelatin into the lumen of the uterus before removal and in 8 instances (66%) he was able to demonstrate the gelatin in the endometriosis of the abdominal scar. In 1 instance the endometrial tract from the tubal stump was 7 cm. long and endometrial sprouts had extended 4 cm. farther through the scar to the skin—a total extension of endometrial glands of 11 cm. beyond the tubal stump.

In 1930 Everett studied the function of the interstitial portion of the tubes with the cornua of the uterus in patients who had no previous surgery. Of 122 tubes studied, 37 (30.3%) showed tubal adenomyosis classified as follows:

	Tubal type	Half and half	Cornu type
Epithelium	20	4	4
Endometrial stroma or stromalike tissue		4	4

Therefore he stated that an operative trauma with a transplantation is not necessary in the region of the uterine cornu.

In the 1930's, Philipp and Huber (95, 154, 155, 156, 157) made a careful study of the tubes and uteri from 83 patients who had had pelvic or abdominal endometriosis. They found that 19 of these had endometrial extension from the cornal portion of the uterus into the tubes—14 bilaterally—and that 9 had actual endometrial polyps of the tubes—3 bilaterally. Using hysterosalpingography they studied tubal patency and concluded that, excluding (1) premenstrual closure and (2) closure by submucous fibroids, all closure of the interstitial portion of the tube is due to tubal endometriosis.

They theorized that endometriosis extends outward from the cornal portion of the uterus to the interstitial portion of the tube, causing tubal adenomyosis. From this, bits of healthy endometrial tissue may (1) break off pass out of the tube, and implant on the peritoneum or (2) break off from the serosal surface of the tube and implant elsewhere in the peritoneal cavity.

Philipp and Huber (157) concluded from their studies that in the patients who suffered abdominal endometriosis following tubal endometriosis the condition occurred in four-fifths of them as a result of retrograde tubal migration and implantation on the peritoneum of healthy bits of endometrium, and in one fifth by direct extension through the tubal wall opening out into the peritoneal cavity.

Weyeneth first pointed out that unilateral tubal adenomyosis is frequently accompanied by homologous uterine adenomyosis. For this reason, and because adenomyosis occurs more frequently in association with anomalies of the tubes than in association with previous inflammation of the tubes, Work and Broders consider tubal adenomyosis to be of congenital origin. They also noted that it sometimes occurred unilaterally in patients who had had bilateral salpingitis, and consequently they doubted that inflammation was of primary etiologic importance. In this connection Yin has recently reported 2 cases of adenomyosis uteri with associated congenital uterine anomalies.

Schenken and Burns studied and classified 339 isthmic nodules from the tubes of 208 patients. They concluded that approximately 70 per cent were adenomyomatous lesions of which 67 per cent contained endometrial tissue and the remainder endosalpingian tissue. Rintelen studied the incidence of tubal endometriosis in 513 women who had had no pathological symptoms clinically referable to the uterus or tubes, but upon whom sterilization operations were performed. He compiled the following surprising statistics:

Ages	Number	Cases of Tubal Endometriosis	Percentage of cases in Group
3-20	130	6	4.6
21-30	113	9	7.9
31-40	54	6	11.1
41-45	6	0	0

Work and Broders observed that adenomyosis tends to occur most commonly at the tubouterine junction and that its incidence seems to diminish caudad and cranial from this region. These investigators and others (139-103) have considered the tubouterine junction to be a transitional area where interchange between tubal and uterine mucosal characteristics are the rule rather than the exception and where glandular tissue is more likely than elsewhere to tunnel into the muscularis to cause a hypertrophic response thereof and result in adenomyosis.

Other investigators (18-112-140-173-186) have noted a correlation between the occurrence of tubal adenomyosis and the occurrence of tubal pregnancies. Lash (112) has observed a human ovum within a small tubule in a patient who had tubal adenomyosis. Whether this ovum entered the tubule from the tubal end or through a possible abdominal ostium is not known. Concerning the coincidence of tubal adenomyosis and tubal pregnancy Schaulfer and Wyma report an operation in which they found an interstitial pregnancy in

one tube surrounded by a large decidual reaction and adenomyosis of the interstitial portion of the other tube, also containing a definite decidual reaction. Casler (18) reports that 6 years after removing a right tubal pregnancy and a left cystic ovary he had to operate again on the same patient, this time for removal of another tubal pregnancy within the stump of the right tube. Sammarino made serial sections of 100 tubal pregnancies. In 16 of the tubes he discovered endometriosis. Still other investigators (34-124) have reported coincident occurrence of ovarian pregnancies and ovarian endometriosis in the same ovary and have suggested that ectopic endometrium is an important factor in ectopic implantation of fertilized ova.

Obviously most of these observations are subject to varied interpretation. However the interpretations presented by various investigators seem to indicate that proliferative phenomena occur in the region of the tubouterine junction rather frequently and that the occurrence of endometriosis in conjunction with these phenomena is considerably greater than heretofore suspected.

Probably the correct attitude toward this particular subject was expressed by McKelvey in his review of the five papers by Philipp and Huber. He wrote, "This work is an interesting and perhaps important contribution. While the original (articles) contain much repetition and too much speculation they should certainly be carefully read. The work would seem to justify confirmatory studies."

More specifically it seems fairly well established that adenomyosis occurs with surprising frequency at the tubouterine junction that the epithelium thereof may be uterine type, tubal type or both and may or may not be surrounded by stroma and that the glands thereof may extend through the musculature to the serosa and in some cases, well beyond. Still in the realm of theory, however are the suggestions that bits of healthy tissue break off either from the mucosal surface of adenomyotic areas to migrate out of the tubes, or from the serosal surface of adenomyotic areas to travel elsewhere in the pelvis—in either instance to implant and produce external endometriosis.

D. MALIGNANT CHANGES

Malignant changes within ectopic endometrial lesions are not common.

1. *Carcinomatous change* Hosai and Meeker (94) reported carcinomatous changes within endometriosis of the transverse colon. Other men (1,8) have observed rare carcinomatous changes in ectopic endometrial tissue.

2 *Sarcomatous change* A number of authors (17 63 84 135 154) have described an unusual type of uterine endometriosis" which consists almost entirely of stroma. Miller and Tennent described it grossly as a yellow rubbery substance and said that it tends to grow down lymphatics, leaving the walls of the lymphatics dilated but intact. There is a heavy reticulum between the cells, and the blood vessel walls are markedly hypertrophied. TeLande suggests that the name "stromatosis" would be most descriptive of this particular condition. Philipp and Huber mention the hyalolytic power (154) of this type of endometrial change. They mention 1 case and Goodall (63) mentions 2 such cases which subsequently developed sarcoma within this stromal endometriosis, reportedly checked before and after with microscopical sections.

II. FACTORS WHICH MAY STIMULATE THE DEVELOPMENT OF ENDOMETRIOSIS

This subject is for the most part within the realm of theories. First mechanical, then inflammatory and finally hormonal factors will be considered.

A. MECHANICAL FACTORS

1 *Surgery curettage insufflation.* Mechanical transplantation of endometrial tissue during ispyrotomy delivery and curettage has already been considered (see mechanical transplantation theory). There is no doubt that healthy proliferative endometrium can be transplanted, and that it frequently will grow and function in the new site. To study the effect of curettage, Watkins (214) operated upon 8 patients immediately after curettage. In all 8 patients he observed from 5 to 60 c.c. of blood in the cul-de-sac and also blood dripping from the fimbriated ends of the tubes.

Not previously mentioned herein is the theory often suggested but never substantiated, that curettage may instigate the development of adenomyosis uteri.

Nor has the possible role of tubal insufflation been considered to any extent. Spirito forced air through the uteri and tubes of rabbits and guinea pigs on 10 successive days. One hundred and twenty-four days later at autopsy he observed endometrial cysts implanted on the peritoneum, identical in microappearance with those which resulted from surgical transplantation of endometrium in the same species. Consequently he reasoned that the Rubin test may be an instigating factor in external endometriosis, and he pointed out that endometriosis is reported most frequently from the United States and Germany countries

which also report most frequent use of the Rubin test. It should be mentioned that in all except severe cases, endometriosis is observed most frequently by those operators who have trained themselves to recognize it grossly (51 52, 178, 179). Therefore, it seems likely that the increased incidence of reports of endometriosis from the United States and Germany derives from increased interest in the subject and careful observation of operative patients in these countries rather than from other factors. It is conceivable, however that development of a high intrauterine pressure to overcome obstruction during a Rubin test, followed by a sudden gushing of gas out of the tube, with the release of obstruction might be accompanied by transportation of endometrial particles through the tubal lumen, especially if tubal adenomyosis is present.

The physiology and anatomy of the tubes were discussed previously herein (see Implantation theory). Concerning their pathology Goodall (61) considered "praeternatural patulousness of the Fallopian tubes to be a menace to the peritoneal cavity." He cited the histories of several patients who had had pelvic peritonitis in whom he was able to pass gas through the tubes at 20 mm. Hg. and he theorized that the patulousness of the tubes facilitated retrograde passage of infection. However he did not attempt to apply this "praeternatural patulousness" to the retrograde menstruation theory of endometriosis, and it is pertinent to point out that these tests were not made at the time of menstruation when tubes are most resistant to retrograde flow (166).

2 *Pathological anatomy of the genital canal.* Uterine retrodisplacement. It is the opinion of many authors (31 41 111 152 214, 215, 216) that retrodisplacement of the uterus predisposes to retrograde menstruation. Watkins (214, 215) operated upon 8 women who had retrodisplaced uteri during menstruation, and observed blood dripping from the tubes in all 8. Examination of the blood in the cul-de-sac was reported as showing red blood cells, leucocytes, and endometrial cells. Upon 11 other patients with retrodisplaced uteri Watkins used the following procedure immediately prior to operation with a 2-way cannula he sucked 1 per cent methylene blue into the uteri under negative pressure. About 5 c.c. of the solution were retained in each instance. At operation he observed that 5 patients had closed tubes, 4 patients with open tubes had mild to moderate staining of the fluid in the cul-de-sac, 1 patient, with open tubes, had no staining of the fluid in the cul-de-sac and in 1 patient with large myomas the dye was not retained in the uterine cavity

Watkins also made several unsuccessful attempts to instill dye into upright uterus.

These observations were made with the patient lying on her back. With the body in such a position gravity favors the retrograde (transtubal) flow of intrauterine fluid. However if the retrodisplacement is not of third degree and the patient is in any other standard position i.e. standing, sitting or lying prone gravity is more likely to favor the normal flow of intrauterine fluid through the cervical canal, provided no cervical obstruction exists, for the cervix will then be lower than the uterine lumen.

Polak and Stacy determined that approximately 20 per cent of all women have retrodisplaced uterus and of these only about one-sixth have dysmenorrhea (199). Fallas and Rosenblum report some degree of uterine retrodisplacement in 52.6 per cent of 260 patients with endometriosis, but Haydon reports uterine retrodisplacement in only 14 per cent of 569, and Payne in only 7 per cent of 307 patients with this condition. (It should be noted here that some observers think that dense adhesions between the posterior wall of the uterus and endometrotic lesions in the posterior cul-de-sac actually produce uterine retrodisplacement).

From these sundry observations it seems likely that a sufficient degree of primary uterine retrodisplacement may facilitate the flow of intrauterine fluid out through the tubes, provided the subject be in supine position. More than this cannot be concluded.

Cervical Obstruction. Watkins (216) pointed out that sharp antelexion or retroflexion of the body of the uterus on the cervix would cause constriction of the cervical lumen. Curtis (29, 30) has repeatedly demonstrated that cervical strictures may follow endocervicitis or cervical instrumentation (especially cautery) or less frequently a tumor encroaching on the cervical lumen. There are numerous reports of instances of congenital atresia of the cervix or vagina (8, 46, 55, 97). If severe enough many of these lesions will obstruct normal outflow through the cervix and vagina, and tend to cause retrograde flow through the tubes. However in the last mentioned congenital atresias of the lower genital canal, it is remarkable how much dilatation of the vagina takes place before hematometra develops, how much dilatation of the cervix and uterus takes place before hematosalpinx develops, and how much of the latter occurs before a chocolate cyst involving the fimbria and ovary develops. This seems to indicate that retrograde menstruation is not a simple and easy process. Bernstein and Walter report 10 instances of congenital atresia of the lower genital

canal among which 2 instances of pelvic endometriosis were observed. They also report 9 instances of acquired atresia of the lower genital canal among which 2 instances of adenomyosis and 1 instance of pelvic endometriosis were observed—totaling 5 or 26.3 per cent, of the 19 operative cases. Holmes (92) reports the incidence of endometriosis among all gynecological patients who submit to abdominal operations as ranging from 21.8 per cent (Sampson) to 26.0 per cent (Holmes) to 32.0 per cent (Meigs). These figures do not indicate an increased incidence of endometriosis among the 19 patients who had congenital or acquired atresias of the lower genital canal despite frequent hematocolpos, hematometra and hematosalpinx.

3. Pregnancy. Meigs (126) reported that mild adenomyosis is more common in women who have had multiple pregnancies, according to statistics at the Massachusetts General Hospital. Scott reported 6 instances of adenomyosis and coincident spontaneous rupture of the uterus during pregnancy. Sackett reported the history of a woman whose uterus contracted well during her first cesarean section but would not contract at all during her second section, 2½ years later. Hysterectomy was performed and marked adenomyosis with decidual reaction therein was discovered. Frankl (48) states that symptomatic internal endometriosis is most commonly found in the age group from 41 to 50 whereas external endometriosis is most commonly found during the preceding decade. Bloom writes: "In pregnancy the connective tissue of the uterus becomes more abundant and succulent, which causes considerable loosening of coherence between muscle bundles."

However if pregnancy is a factor in the development of adenomyosis, it still is not known on what basis, mechanical or hormonal or both.

B INFLAMMATORY FACTORS

Frankl (48) has stated that there is very definite evidence of inflammation around external endometriosis. Sampson (178, 179) theorized that regurgitation of menstrual blood is especially irritating to the pelvic peritoneum stimulating in it an inflammatory condition which facilitates implantation of endometrial particles thereon. Meyer (132) theorized that following pelvic inflammation the healing process runs riot causing metaplasia of the epithelium and subepithelial cells into endometrial like tissues. Apparently regardless of one's theories concerning histogenesis, a number of investigators have postulated the intercession of an inflammatory process as abetting the development of endometriosis.

It is a well known fact that there are inflammatory changes in and around active endometrial lesions. However these changes are a local response to a semi invasive tissue in a foreign location, aggravated periodically by the menstrual cycle. Therefore, it seems like placing the cart before the horse to say that these inflammatory changes cause, or are a factor in causing the development of endometriosis.

C. HORMONAL FACTORS

Here the flight of theories approaches a zenith. Conversely although inferential evidence is abundant, one can plumb the depths, yet seldom find a solid foundation of fact.

A number of authors (3, 35 125 144 193 222) have written that the primary factor initiating the development of endometriosis is hormonal in nature. As early as 1931 Novak (144) theorized, "The sensitizing influence must be of physiological nature, probably bound up with the internal secretion of the female gonads." This theory will be discussed under several subheadings.

1 *Response of ectopic endometrium to ovarian hormones* The ability of active endometrial lesions to respond to ovarian hormones in a manner similar to the response of uterine endometrium has been demonstrated histologically by several authors (59 64, 149) Goldstone and Fogelson's photomicrographs, taken from endometrial lesions of the rectovaginal septum, not only show all phases (proliferative, secretory menstrual) of endometrial response to ovarian hormones but also show a gland with cells of tubal type epithelium.

Faulkner and Reimenschneider report the case of a "postmenopausal" woman whose rectovaginal endometriosis was reactivated by therapy with stilbestrol (1 mgm. per day for 15 days). She suffered rectal bleeding sufficient to cause a drop in the red blood count to 2,570,000. The bleeding stopped when the stilbestrol was discontinued.

Weinstein *et al* and Hobbs and Bortnick (88, 89) demonstrated that endometrial transplants in rabbits responded to injections of estrogens in the same manner as the uterine endometrium, and the latter authors also noted decidual reactions in endometrial transplants of pregnant animals. While transplanting endometrial tissue in rabbits, Neumann found that ectopic endometrial cysts would develop in his normal rabbits, but none were found in animals previously castrated. However Jacobson (99) found endometrial cysts which were developing in rabbits which he castrated at the time of the transplantation but the cyst walls were much thinner than were those which developed in normal rabbits.

It must be concluded that ectopic endometrial tissues and regular endometrium respond to hormones in a similar manner. It is argued that, if the ovarian hormones influence the development of intrauterine endometrium, it is reasonable to theorize that the same hormones would occasionally influence the development of embryonically related cells outside the uterine endometrium in such a manner that ectopic endometrium might result. There is no proof that this is impossible. However the ability to stimulate already existing tissue to physiological activity is not the same nor even necessarily related to the ability to initiate the development of new tissue.

2 *Relative tissue sensitivity to hormonal stimulation* (a) Goodall (63) and others have indicated that the lesions of endometriosis which do not show cyclic activity in conjunction with the uterine endometrium are derived from the so-called insensitive basal layer while the more active endometriotic lesions are derived from the superficial two-thirds of the endometrium which responds to hormonal stimuli by menstruating. However Hartman excised the endometrium from monkeys as completely as possible, certainly leaving behind only a few fragments of the basal layer and he found completely regenerated, functional endometrium in these monkeys from 14 to 20 days after operation. This was repeated 4 times in one animal. Many of the animals so treated subsequently became pregnant, one animal 3 times, and delivered normal fetuses. Certainly in these monkeys cells derived from basal tissue responded normally to ovarian hormones.

A more likely explanation for variation in activity of ectopic endometrium is available. Bar telmez (6 7) studied human uteri removed at the time of menstruation and discovered that different areas in the superficial endometrium of a single uterus responded differently both in time and degree. Concerning ectopic endometrial tissue, the corollary explanation is obvious, although the reason for differing sensitivity is not known.

Ranging further into theory if ectopic endometrium evolves by a process of metaplasia from peritoneal and subserosal cells, at any one time there must be several stages of maturity represented in different lesions. Theoretically the most differentiated tissue would respond most readily to hormonal stimulation and vice versa.

(b) Goodall (63) mentions that he frequently finds the pelvic peritoneum perceptibly thicker in endometriotic patients than in others. He calls this pelvic sclerosis, differentiates it from scar tissue, and says it is due to the same hormonal stimuli which facilitate the development of endo-

metrosis If there is any basis for the suggestions of Novak (145) and Allen (3) that endometriosis is a manifestation of cellular metaplasia following hormonal stimuli, then surely the serosa and subserosa of the pelvic and lower abdominal peritoneum should show more susceptibility to the ovarian hormones than should more distant tissues of the body because of close embryonic relationship to endometrial tissue—as shown by Gruenwald (67 68 69 70, 71). In this connection Scott points out that as the distance from the ovary increases, the tendency for subperitoneal tissues to produce a decidual reaction decreases and Novak (144) notes that the distribution of decidual plaques is almost identical with that of endometriosis. As noted above these suggestions are all of an inferential nature.

3 Age incidence The age frequency graph (Fig 6) adapted from Fallas and Rosenblum's statistics demonstrates the usual ages at which patients suffering from external or internal endometriosis come to operation. Statistics of other investigators (1 106 151) agree essentially with the age incidence depicted.

Although patients suffering from endometriosis have come to operation most frequently during the fourth and fifth decades of life, Fallon (42) has recently reported that 4 per cent of the last 225 endometriosis patients upon whom he operated have been teen age girls. Many of these gave histories of increasing dysmenorrhea. In the remainder of the endometriosis was discovered at operation. In a routine examination of supposedly normal tubes, Runtelen found tubal endometriosis in 4.61 per cent of 130 teen age girls. Holmes (92) suggests that increasing dysmenorrhea and pelvic pain occurring in the second decade of life may often represent symptoms of the early stages of endometriosis more severe symptoms leading to operation in the third and fourth decades represent later stages of the disease.

Obviously endometriosis occurs during the sexually active period of life, starting after puberty and stopping in most instances (65 193) at the menopause. It is perhaps too easy to assume then, that those hormonal factors which produce sexual maturity in women also may produce endometriosis. Attention should again be called to the fact that stimulation of growth of an existing structure is not the same as neogenesis of that structure.

4 Infertility Gardner (52) writes, "Often endometriosis is first recognized when a search is being made for a woman's failure to conceive." Numerous authors (1 19 21 36 41 43 52 107 109 118 194 195) agree that the percentage of

Fig. 6. Age incidence of endometriosis—adapted from Fallas and Rosenblum (41). Patients in whom only external endometriosis was found came to operation most frequently at age 35. Internal endometriosis, at age 45. Both combined in same patients, at age 40. The majority of all endometriosis patients come to operation between the ages of 35 and 50. External endometriosis 95 cases, in patient (++++). 129 cases both types in same patient (++++). 36 cases all cases of endometriosis—260 cases.

infertility among these patients is much higher than normal. Absolute sterility is variously estimated at from 20 to 70 per cent. Likewise sterility at from 50 to 90 per cent. Likewise authors are somewhat dubious about the ability of these patients to conceive even after corrective surgery. Lock and Meyers summarized the reports of various operators (21 77 107 152 209). Among these, by far the best results were obtained by Turunen (209). Of 200 endometriosis-sterility patients he operated upon, about 32 per cent were able to conceive postoperatively, however no record is made of the number of living term babies which accrued.

Again the question of precedence arises—the cart, or the horse? Is this infertility caused by the endometriosis, per se, or is it caused by the same factors which initiate the development of endometriosis? The answer is not known but the fact that this infertility often is noted early in sexual life, preceding rather than following the known development of endometriosis (43) favors the latter explanation and King (108) uses this as an argument in favor of his ovarian metaplasia theory. Lack of ovulation is most frequently given as the cause of sterility in these patients but no study has been undertaken to prove or disprove this statement.

No one knows how many women with endometriosis have become pregnant because no one knows how many women have mild, more or less asymptomatic endometriosis. Therefore, statistics correlating infertility and endometriosis are only significant with relation to those more severe cases which come to surgery and which are proved pathologically.

5 *Coincident pelvic pathology* Many authors (1 3 36 41 47 63 77 95 109 117 136 152 195, 222) report that the incidence of fibromyoma of the uterus is high among patients who have endometriosis, ranging from 22 to 73 per cent. (Curtis [31] records that according to autopsy reports 'one out of every five women of mature years has uterine myomata' [30%], but he mentions that many of these are too minute to be clinically significant.) Many authors (41 47, 77 103 117 136 222) also report an increased incidence of endometrial hyperplasia, from 10 to 71%, of endometrial polyps, from 8 to 14% and of follicular cysts, from 14 to 22%, among endometriosis patients who have been operated on. From these and similar statistics (196) some writers (35 103 222) have inferred that endometriosis is but one of several manifestations of hyperestrinism displayed by some women. However Sturgis points out that the diagnosis of endometriosis was made in only 15.7 per cent of 51 patients who had endometriosis. The remaining 84.3 per cent of the patients were operated upon for other pelvic disease, such as myoma and ovarian cysts at which operations the endometriosis was incidentally discovered. Other writers (21 41 43 51 52) have remarked upon the infrequency with which a pre-operative diagnosis of endometriosis can be made with any degree of certainty. Thus, it seems likely that the statistical correlations noted may be more apparent than real, since in many instances the patients were probably operated upon because of symptoms and findings produced by their myomas, ovarian cysts, uterine polyps, or endometrial hyperplasia, with endometriosis as an incidental finding at operation. There may be as many women without myomas, but with endometriosis, who have no symptoms. Therefore, these patients would not be operated upon, and, thus, their endometriosis would not be discovered.

Consequently no conclusion can be drawn from the relative statistics listed concerning the etiology of endometriosis.

6 *Cyclic stimulation theory* Meigs (125 126) noted that whereas endometriosis was observed in from 28 to 50 per cent of private gynecological operative patients, it was observed in from only 5 to 8 per cent of charity gynecological operative

patients. He observed that the most fundamental difference between these two groups was the tendency toward later marriage and less frequent pregnancies among the private patients. He theorized that the resultant, cyclic, hormonal stimulation, uninterrupted by pregnancy and lactation during the first 17 to 27 menstrual years in many of his cases, was an important factor in the development of endometriosis. He postulated that earlier marriages and less contraception would protect somewhat against the development of endometriosis by insuring earlier and repeated pregnancies followed by lactation. In this connection, Fallon *et al* (43) noted that only 1 of 200 patients with endometriosis had been pregnant within 5 years prior to their operation.

This is an interesting theory with many ramifications, both medical and sociological. However, it does seem to ignore the relatively tremendous concentrations of hormones which are produced during pregnancy. Proof or disproof of this theory may be possible after another generation of observation and correlation.

III. SUMMARY

It has been well established that endometrial tissue will extend outward from its normal location, either between muscle bundles or through lymphatics. This extension may on occasion proceed beyond the confines of the uterus. There is some evidence that the uterotubal junction is the most frequent site of such activity.

Likewise, particles of healthy endometrium can be surgically transplanted, and will grow in ectopic sites. Theoretically such healthy endometrial particles may (1) break off from the serosal surface of direct extension endometriosis and spontaneously transplant themselves to some other serosal surface, or (2) break off from uterotubal adenomyosis, either spontaneously or as a result of intrauterine trauma and may travel out through the tube spontaneously or more likely after intrauterine trauma, to implant on the peritoneum.

Theories involving retrograde menstruation are still held in doubt because of the inability to present conclusive proof that the viability of menstrually discharged, endometrial particles is adequate to support implantation.

The theory that all derivatives of the embryonic coelomic lining retain the potential ability to develop endometrial-like tissue by a process of metaplasia when properly stimulated has the following advantages:

- 1 It is based on known embryology
- 2 It permits a physiological explanation for the development of endometriosis.

IV APPENDIX

A OUTLINE HISTORY OF LITERATURE CONCERNING ENDOMETRIOSIS CHRONOLOGICALLY ARRANGED

Date	Name	Ref. No	Contribution	Date	Name	Ref. N	Contribution
1860	Rokitansky von	65	First known record concerning endometriosis described an adenoma	1909	Goddard	57	First to report endometriosis of the umbilicus as such
1870	Waldyer	912	Suggested that such lesions might originate from germinal epithelium of ovary	1910	Meyer	3	Enlarged on the serosal metaplasia theory suggesting local inflammation as an exciting factor
1887	Walker	13	Reported ectopic decidual reaction of pelvic peritoneum coincident with uterine pregnancy	1921	Sampson	74, 75, 76	Theorized that retrograde menstruation of bits of endometrium through the tubes was followed by implantation and growth of endometriosis on ovaries and pelvic peritoneum
1888	Russell	170, 17	First to report endometrial tissue in ovaries theorized origin from misplaced paramesonephric tissue	1924	Hallam	72, 73	Theorized that endometrial tissue metastasized by way of lymphatics
1893	Recklinghausen, von	16, 162	Theorized that origin of adenomyoma is from mesonephric duct cell rests	1925	Kerck	100	First to report endometriosis of the bladder
1896	Pick	58, 159	Theorized that origin of ovarian endometriosis is from mesonephric duct cell rests	1926	Novak	43	Suggested that some endocrine factor may induce serosal metaplasia
1896	Isenack	96	Suggested that the endometrial elements of adenomyoma may develop from the peritoneal surface of the uterus	1927	Schiller	89	Suggested that endothelial and other cells of mesothelial origin might undergo heteroplasia to form endometriosis
1896	Cullen	24	First to report adenomyoma of the round ligament, as such Round ligament tumor reported by 5 other men (Coulson 1899, Eichenbaum 1899, Leopold 1900, Roustan 1904, and Martin 1905 may have been adenomyomas)	1931	Kling	68	Theorized that ovarian endometriosis resulted from metaplasia within uterine follicles and corpus luteum cysts
1897	Ries	103	First to report endometrial tissue in the lymphatics	1936-39	McEpp and Riber	54, 55, 56, 157	Theorized that tubal endometriosis was the first step in the development of pelvic endometriosis
1898	Lockstaedt	9	Demonstrated continuity between endometriosis and subserosal endometriosis	1936-39	Navratil	37, 38	Reported endometriosis of the arm, suggesting venous metastasis
1901	Meyer	128	First to report endometriosis in laparotomy scar	1943	Brines and Blain		Theorized that adenomyoma resulted from dedifferentiation of myometrial cells to embryonic forms and redifferentiation to endometrial cell
1908	Meyer	130	First to report intestinal endometrial adenomas	1947-48	Giesen and	67, 68, 69, 70, 71	Demonstrated, microscopically the embryological basis for the reticulo-metaplasia theory
1908	C. Dea	5	Demonstrated that tertiary adenomyoma can occur by direct extension of endometriosis into myometrium				

3 Possible transitional stages have been observed microscopically

4 Spontaneously occurring endometriosis in all known locations can be explained on the basis of this theory

The theory of lymphatic metastasis of endometrial particles is possible but its scope is limited. All lymphatic phenomena thus far observed concerning endometriosis can be explained on the

basis of (1) direct extension through lymphatic spaces, or (2) metaplasia within the lymphatic system.

The theory of venous metastasis of endometrial particles to produce endometriosis in distant parts of the body can be proved only by microscopic observation of an endometrial tumor in lung tissue.

The paramesonephric cell rest theory is feasible but is not at present susceptible to proof

The factors which may stimulate the development of endometriosis are more theoretical than the theories concerning the histogenesis thereof. Suffice it to say that (1) some cases of endometriosis may be induced by pelvic operative or diagnostic procedures (2) it has not been determined whether endometriosis occurs as a consequence of pelvic inflammation or vice versa (3) endometriosis occurs during the sexually active period of a woman's life usually regressing spontaneously after the menopause whether spontaneous or artificial and (4) infertility is higher than average among patients suffering from endometriosis. These last two observations indicate that the ovarian hormones are related to endometriosis. Whether the relationship is that of an initial stimulating force or simply that of an incidental physiological function is not known.

This subject like so many subjects in medicine is weighted with many worthy thoughts, but few golden truths. One excellent consequence of the widespread interest in endometriosis is that this condition is being recognized more frequently now than previously at the operating table. Further knowledge of its etiology may facilitate proper diagnosis earlier in the disease than is now possible.

The writer wishes to acknowledge most gratefully the expert recommendations, in suitable and not suitable matters, of Louis Dr. R. Greene.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Ocular Involvement in Rats on Diets Deficient in Amino Acids: I. Tryptophan. ARMANDO FERRARO, LEON ROIZIN, ISAACOW GIVNER, and MORGAN WORTHY. *Arch. Ophth.*, Chic., 1947 38 331

During the past 4 years the authors have been engaged in a study of the effects of various amino acid-deficient diets on the growth, development, and morphology of various body tissues and organs and on the endocrine glands and nervous system in rats. Up to the present they have observed ocular involvement with diets deficient in tryptophan and valine. The experiments confirm, extend, and complete some of the observations made by earlier workers following their experiments with rats maintained on tryptophan-deficient diets.

In the present article the authors pay particular attention to the development and the histologic character of the cataractous changes in the lens associated with this deficiency.

The ocular changes, in order of their appearance may be described thus:

1. In younger animals there appeared spectacle eyes, conjunctivitis, superficial vascularization of the cornea and occasionally cataractous changes in the lens. This group of animals did not resist for long on the deficient diet and generally died before presenting specific symptoms of tryptophan deficiency noticeable to a greater degree in the next group.

2. In rats of greater development, spectacle eyes were apparent at times, but less frequently, and in a less pronounced degree than in younger group. However, corneal vascularization and particularly various degrees of cataractous changes in the lens were more constant.

3. In a third group comprising adult rats weighing 300 gm, spectacle eyes and conjunctivitis were noted only occasionally, whereas vascularization of the cornea was more commonly observed.

The authors believe, therefore, that the development of cataractous changes in the lens occurred immediately before the rats reached the adult stage. They consider it an established fact that tryptophan is able to prevent, improve and cure the general clinical as well as some of the ocular symptoms produced experimentally by tryptophan-deficient diets. These changes are of two types: (1) the earlier ones characterized chiefly by water splitting of the lens fibers and vacuolation, changes which the experiments have established to be reversible under tryptophan treatment, and (2) the more advanced ones leading to disorganization of the structure of the lens, changes which seem to be irreversible.

J. WOODHULL OVERTON, M.D.

Ocular Changes in Rats on Diets Deficient in Amino Acids: II. Corneal Dystrophy Due to Valine Deficiency. ARMANDO FERRARO, LEON ROIZIN, ISAACOW GIVNER, and MORGAN WORTHY. *Arch. Ophth.*, Chic., 1947 38 342

It has been established that of the 22 most important amino acids, 10 are absolutely essential to growing animals and 8 are necessary for the maintenance of the nitrogen equilibrium in adult man.

In this preliminary communication the authors report their observations on rats reared on a valine deficient diet. They observed that changes develop in the cornea in addition to various changes and structural alterations in other organs which are still the subject of microscopic studies. The corneal changes seem to be the result of edema and progressive degeneration leading gradually to keratinization and disorganization of the epithelial structure of the cornea. These changes are generally encountered in the interpalpebral space. In addition pronounced deep vascularization of the cornea is observed. Slight changes in the lens chiefly vacuolation of the cortex are only occasionally noted.

The structural changes in the eye appear to be reversible. The corneal changes appear to be the more prominent feature of the ocular involvement. The authors feel justified in naming the corneal change nutritional corneal dystrophy.

J. WOODHULL OVERTON, M.D.

Intraocular Foreign Bodies. GEORGE M. HALE, J. *Am. J. Surg.* 1947 335 894.

The author discusses intraocular foreign bodies. He points out that the toxicity of foreign bodies for ocular tissues varies according to their composition. Gold, silver and platinum are well tolerated. Iron and copper oxidize rapidly and result in siderosis bulbi or chalcosis. Lead and zinc are somewhat irritating. Glass, aluminum and plastics are practically inert.

Hale concludes that the presence of an intraocular foreign body in the eye is always a serious matter, the degree of seriousness depending on its location. Immediate extraction of the foreign body is not always necessary. Accurate localization is most essential. Roentgenologic localization should be supplemented with the use of the Berman or Carney locator. The technique of extraction depends on the composition and location of the foreign body and on the condition of the eye. Magnet extraction is preferable but surgical procedures are required for the removal of nonmagnetic foreign bodies. Emergency enucleation of the eyeball is seldom justified.

Chemotherapeutic substances, antibiotics and foreign protein should be administered routinely in

the treatment of all perforating wounds. The regimen found most effective was the administration of penicillin in from 40,000 to 50,000 Oxford unit dosages as soon after injury as possible which were continued until 2,500,000 units had been given.

JOHN ZUCKERMAN M.D.

Use of Air Injections Into Tenon's Capsule for Localization of Orbital Foreign Bodies. B. VJAM. PETERMAN. *Arch Ophthalmol* Chic 61:7 15 660

The author believes that the injection of air into a non-aqueous capsule may be of considerable diagnostic value in the localization of orbital foreign bodies by outlining the contour of the globe and providing a basis for judging their relative positions. From 6 to 10 cubic centimeters of air injected into a non-aqueous capsule, either in the upper or lower quadrant, can displace the position of the known foreign body sufficiently to push the globe forward. Roentgenograms taken on angles or stereoscopic film, which take on shadows or vessels if the foreign body is metallic, it will be separated from the globe by the air even if the foreign body is not metallic. The technique is described in the preceding paper. The use of a large dose of roentgen radiation in cases in which metal is present is not indicated. R. H. LAWSON, M.D.

Preliminary Report F N D 1 Tech
Opth Chrc 047 15 05

The author describes a surgical procedure for the cure of hypertropia associated with overaction of the superior oblique muscle. Overaction of this superior oblique muscle occurs rarely as a primary lesion but generally is due to a weakening of the homolateral inferior oblique muscle or of the contralateral inferior rectus muscle. These patients experience ocular discomfort, headaches, a rural diplopia, and difficulty in reading. It is characterized by head tilting and by vertical deviation which increases in adduction and in the lower temporal fields. If the vertical deviation is 5 prism diopters or less, prisms or fusion exercises may be sufficient. Operative treatment is indicated if symptoms persist. As a general rule all surgical procedures in the vertically acting extraocular muscles are directed toward (1) strengthening the weak muscle, (2) weakening the direct antagonists, or (3) weakening the yoke muscle. Tenotomy or tenectomy of the superior oblique muscle had never been performed previously to relieve hypertropia in a patient with overaction of the oblique muscles. Most ophthalmic surgeons have questioned its advisability. The author believes it is a safe, simple, satisfactory procedure and that it should be performed whenever the muscle is overactive and the symptoms of the hypertropia cannot be relieved by nonoperative means. In cases of paralysis of the third nerve and in cases of so-called paralysis of elevation, the superior oblique muscle should be tenectomized.

Anatomically the sheath of the tendon of the superior oblique muscle has many attachments to

the adjacent muscles and surrounding tissue. There are also many delicate areolar tissue fibrillae connecting the tendon to its sheath. It is believed these attachments allow the muscle tendon to be cut with only a weakening of its action and not a paralysis. The surgical procedure can be done under either a local or general anesthetic. The conjunctiva and Tenon's capsule are incised in the superior nasal fornix and the tissue between Tenon's capsule and the sclera is undermined posteriorly. A muscle hook is passed from 10 to 12 millimeters backward between Tenon's capsule and the sclera. With the hook flat against the latter, the point is then turned upward toward the roof of the orbit so as to engage the reflected tendon and sheath of the superior oblique muscle. The tendon can be identified by its color and by palpation under traction. Depending on the amount of hyperphoria present the tendon may be incised or a variable amount of it may be removed. The conjunctiva is then closed.

The patients were divided into three groups. The first group was made up of those who had had a simple tenotomy lateral of the superior rectus muscle, and in whom good results had been obtained in only 1 case out of 4. The second group was made up of 1 patient who had had a simple tenotomy on the lateral side of the superior rectus muscle in which group there were only 2 failures, the 4 remaining patients having from 13 to 15 prism diopters of correction in the field of greatest action of the superior rectus muscle. In the third group there were 10 patients who had had tenectomy without a simple failure the amount of correction in the field of greatest action varying from 10 to 15 prism diopters.

Trachoma & Possible Carrier Status MARTIN BO-
trch Update Chlc 047 35 450.

The author attempted to determine the morbidity rate of a possible carrier state of trachoma among the natives of Fiji, and to determine the spread of trachoma in America troops stationed in that region.

1. Fifty American soldiers who had lived there under strict military sanitation for over a year were examined and although nearly all showed mild conjunctival hyperemia none was found to have trachoma and no inclusion bodies were found on any slide made.

The 100 rats used were not representative of the population but had been selected as laborers at the Army installation. Twenty-two per cent showed evidence of active trachoma with 15 of these showing brownish filaments after inclusion bodies.

Twenty-seven natives without clinical evidence of trachoma also showed in one or both eyes inclusion bodies which were microscopically indistinguishable from those observed in smears from trachomatous patients. Iclusion bodies of other diseases which could be taken for trachoma do not exist in this locality. Follow-up observations on this trachomatous-free group with inclusion bodies

failed to show any change over a period of 4 months. Since these natives did not develop trachoma after the 5 to 12 day incubation period it was suggested that they were carriers. The author doubted that these patients could have been infected and had a spontaneous cure without clinical evidence of the disease.

ROGER H. JOHNSON M.D.

An Unusual Case of Symmetrical, Bilateral, Non-traumatic Iris Prolapse M. L. NAMRA. *Brit. J. Ophth.* 1947 31 700.

This is a case report of a 22 year old negro woman who had had burning of both eyes followed by a purulent discharge and intense photophobia. On first examination 2 weeks after the onset of symptoms she was found to have a staphyloma in the upper quadrant of each eye. The pupils were irregular and drawn upward.

One month following her original symptoms, examination showed a bilateral iris prolapse between 11 and 1 o'clock. The pupils were drawn upward but were not involved in the prolapse. The eyes were otherwise normal and there were no signs of inflammation.

The prolapsed irides were seared with the electric cautery and a thick conjunctival flap was drawn over each opening. The results were good.

The author surmised that an acute conjunctival infection was complicated by the formation of corneal ulcers, with their subsequent rupture and prolapse of the irides.

ROGER H. JOHNSON M.D.

Postoperative Complications of Cataract Extraction. WILLIAM F. HUGHES JR., and WILLIAM CONZMAY OWENS. *Arch. Ophth. Chic.* 1947 38 577

The authors report the postoperative complications of cataract extraction. They found that the majority of postoperative complications were related to the type of operation performed rather than to the general systemic condition of the patient. The following routine technique of cataract extraction is now used at the Wilmer Institute.

The pupil is dilated with a solution of 2 per cent homatropine the anesthesia and akinesia are obtained by the Van Lint technique or the O'Brien block, by retrobulbar injection of 1.5 to 2 c.c. of 2 per cent procaine hydrochloride and repeated instillations of 0.5 per cent tetracaine hydrochloride (the intravenous administration of sodium pentothal may be used for apprehensive or unco-operative patients) a superior rectus traction suture is inserted, a conjunctival flap about 3 to 4 mm. is dissected down to the limbus from 10 to 1 o'clock, a shelving horizontal groove is made by means of a Lundsgaard knife halfway through the corneoscleral tissue at the base of the conjunctival flap from 11 to 1 o'clock two corneoscleral sutures of No. 000000 braided silk are inserted through these grooves according to the technique of McLean the corneal incision is made with a Graefe knife (or, if desired, with a keratome) the incision may be enlarged with scissors one per-

ipheral iridotomy is made between the two sutures at 12 o'clock the lens capsule is grasped with intra-capsular forceps at 6 o'clock, under the iris and the lens is delivered by tumbling through the round pupil with counterpressure applied below the corneoscleral sutures are tied the iris is repositioned and the conjunctival flap is restored to its normal position with silk sutures. Physostigmine salicylate 0.25 per cent solution is instilled and penicillin ointment introduced. The patient is allowed out of bed within 72 hours after operation. The pupil is dilated with atropine on the first or the second postoperative day. The sutures are removed on the eleventh day and the patient is discharged the next day.

Hughes and Owens studied the causes treatment and prognosis of complications following cataract extraction in a series of 2,086 cases. They conclude that the complications resulting from insecure closure of the corneal wound can be prevented in most cases by the use of two silk corneoscleral sutures. These complications which include gaping with prolapse of the vitreous or iris delayed re-formation and hemorrhage into the anterior chamber can be treated by excision of any vitreous, lens capsule or iris tissue caught in the lips of the wound and closure by means of a conjunctival flap or additional corneoscleral sutures. Should the anterior chamber not re-form within 7 to 10 days air should be injected into it.

Postoperative iridocyclitis occurs when lens cortex is retained in patients who acquire a hypersensitivity to the retained lens cortex. These patients respond to intracutaneous desensitization and surgical removal of the lens material. Iridocyclitis may also result from loss of vitreous at operation or from late rupture of the hyaloid membrane.

Secondary glaucoma may follow postoperative iridocyclitis. Surgical intervention rather than miotics is usually required.

Detachment of the retina is associated with loss of vitreous at the time of operation. The results obtained with perforating diathermy were poor if more than 2 months had elapsed after the onset of the detachment or if the retina was not replaced after withdrawal of subretinal fluid. In the latter event injection of isotonic solution of sodium chloride into the anterior chamber may be tried as a means of forcing the retina back into position.

JOSHUA ZUCKERMAN, M.D.

A Case of Pseudoglaucoma J. A. MAGNUS. *Brit. J. Ophth.* 1947 31 693

The author reports a case of pseudoglaucoma. Many cases have been reported previously in the literature which presented typical glaucomatous cupping but without any increase in the intraocular pressure. The case presented by Magnus was associated with calcification of the internal carotid artery of the patient who was 74 years of age, and had a blood pressure of 160/80. Both fundi revealed deeply cupped slightly pale disks. Provocative testing by keeping the patient in a dark room for an

tend to be wide at the top and taper toward the lobule, being roughly triangular.

Since the earliest conception of the protruding ear was that it stood out directly from the skull, it is natural that the first attempts at correction attempted to pull the entire ear close to the head. When the true nature of the deformity was realized an entirely different approach developed. We may then divide correction methods into two groups, the first of which is of historical interest only. Two groups are presented for classification: group 1 comprises those methods designed to bring the entire ear closer to the head; group 2 comprises those methods designed to produce a normal anthelix and preserve the essentially normal contours of the other parts.

Luckett's introduction of a new approach to the problem of the protruding ear greatly improved results. Any of the various operations based on this fundamental concept produce acceptable ears. It has been the author's experience that no one method is universally applicable to all cases. Generally speaking, the use of mattress sutures, Lembert sutures, gauze bolsters and special materials such as steel wire seems unnecessary if the cartilage of the ear has been adequately weakened and adjusted.

The author describes in detail his method of correction. It is illustrated with 6 figures and there are many accompanying photographs of various deformities.

JOHN F. DELANEY, M.D.

Endopreauricular Surgery in the Treatment of Chronic Otitis Media (La cirugía endopreauricular en el tratamiento de las otitis medias crónicas)

AGUIERO LATORRE AGUIERO *Rev. otorrinol.*, 1947 7 57

Aguiero relates his experience with the endopreauricular operation for chronic otitis media in 38 patients ranging from 11 to 50 years of age. There were 9 males and 28 females. The Leinhardt and Kettel techniques were employed under local anesthesia with a 2 per cent novocaine. The incision and operative procedure are illustrated in the accompanying sketches (Figs. 1, 2, 3 and 4).

Constant irrigation is done with normal saline solution throughout the operation, which keeps the field clean and promotes good vision. The post-operative results are good. Besides the esthetic scar value obtained by this procedure, there is little rise in temperature, no significant pain and the minor character of the effect upon the patient is such that there is no contraindication even in cardiac patients. One of the patients had malignant endocarditis. Of the 38 patients operated upon, only 6 have persistent otorrhea. There was no case of perichondritis, facial paralysis, or meningitis or sinus complication.

The author stresses preoperative x-ray studies and the importance of small cells found around the mastoid antrum in the region of Citelli's angle. These must be removed as they may be the cause of failure in eradicating the purulent otorrhea. The hearing of

Fig. 3

Fig. 4

the individuals operated upon depends on the injury sustained by the inner ear before the operation. These reasons are advanced to show the advantage of this type of operation over that with the retroauricular approach.

STEPHEN A. ZIEMAN, M.D.

Carcinoma of the Middle Ear and Mastoid Process.

ARNOLD A. GROSSMAN, W. ALLEN DOWNHILL and MAURICE F. SUTTMAN *Ann. Otol. Rhinol.*, 1947 56 709.

Carcinoma involving the middle ear is usually not seen until late, at which time it is difficult to determine its site of origin. By the use of the tympanic membrane as a line of anatomical delineation these neoplasms may be classified as (1) those arising in the middle ear and mastoid, (2) those arising in the auditory canal and aural canal, and (3) those which involve all of these structures, which makes their site of origin undeterminable.

The most common symptoms are otorrhea of long standing and pain out of all proportion to the clinical findings. Bleeding and ulceration are common. Facial paralysis occurred eventually in all of the cases. The labyrinthine capsule is relatively resistant to invasion. Dysphagia and inarticulate speech develop when the jugular bulb region is involved. Direct extension is common along the external auditory canal to and from the tympanum. Regional lymph node metastasis occurs only late. Early diagnosis depends upon early biopsy of recurring suspicious granulation tissue which appears in the auditory canal.

surface of Shrapnell's membrane and (3) that bone sand and bone alivers, which are products of the operation, be completely removed as if left present, they accelerate bone regeneration.

However surgeons performing this operation still find numerous closures of the fenestra. The author has attempted to discourage the formation of connective tissue around the rim of the fenestra so as to avoid its closure. This is accomplished by (1) controlled bleeding in the surgical wound and creating the fenestra in an absolutely bloodless field (2) never sealing the fenestra with the tympanomeatal membrane in the presence of even the smallest amount of bleeding anywhere in the surgical wound, and (3) changing the site of the fenestra. He changed the site of the fenestra by making the fenestration directly into the vestibule instead of into the lumen of the external semicircular canal posterior to the ampulla. In this way a larger opening could be made perhaps giving the fenestra less chance of closing.

This new technique, known as the nov-ovalis technique has made it possible to improve air conduction hearing to the practical level in about 80 per cent of the most carefully chosen cases however the continuous maintenance of adequate hearing for more than 2 years and permanently thereafter has been obtained in only about 75 per cent of cases postoperatively.

Further techniques must be developed to aid in the diagnosis of cases best suited for the operation. The tests needed are (1) a practical and specific objective test for the accurate preoperative determination of the unused reservoir of cochlear nerve function existing in the ear chosen for fenestration (2) a technique embracing a definitely proven specific way for preventing osteogenesis from arising postoperatively in any of the three histologic layers of the freshly injured bony walls of each and every newly created fenestra. It is only when these can be found that the end results of the operation can be reasonably predicted.

The author discusses briefly what he has done to accomplish the development of an objective means of testing hearing, i.e. the determination of bone conduction with the use of tuning forks by watching very carefully the actions of the patient, which will do more towards telling him when the patient is no longer able to bear the tuning fork than any remark on the part of the patient as many patients will state that they hear the tone long after they have stopped hearing it.

What has been done towards the development of specific means to prevent osteogenic closure of the newly created fenestra is discussed. Observations made in human ears during revisions of osteogenetically closed fenestrae and histologic studies in the rhesus monkey revealed that osteogenesis takes place in the endosteal periotic and enchondral layers of the fenestral rim. In view of these observations it became quite obvious that if a newly created fenestra was to remain open permanently means and ways of

hindering osteogenic repair locally within all the three histologic layers of the bony rim would have to be devised. The histologic structure must be devitalized and inactivated without being destroyed.

In his attempt to force healing of the freshly cut bony walls of the fenestra without osteogenic repair by instituting physical resistance to prevent the onset and spread of osteogenesis the author employed the following means:

1 Soft tissue resistance by pressing the tympanomeatal membrane tightly into the fenestral gap when sealing the newly created fenestra. (This however proved to be of little value.)

2 Physical resistance with an inert metal obturator frame (The author still believes this is an excellent way to prevent osteogenesis but it can not be satisfactorily used until a method can be developed of creating a fenestra of standard size and shape in the bony labyrinth so that a prefabricated inert metal frame of the same size can be inserted with ease.)

3 Physical resistance with a cartilage stopple (He employed this in 750 cases with much evidence that the technique when quickly applied prevents inflammation of the labyrinth and osteogenesis. However many of the patients lost their hearing and it was shown that the decrease in hearing is caused by a fibrous adhesion between the edges of the fenestra and the cartilage or by osteogenesis covering the cartilage stopple if it did not extend deep enough into the fenestra or was not sufficiently elevated from the outside surface. Also in some cases the stopple was too firmly applied into the fenestra and hearing was not satisfactory from the first. The author has therefore abandoned this technique.)

Attempts were made to prevent osteogenesis according to the second principle—by devitalizing and inactivating the histologic structure responsible for it. The author in a number of cases polished the edges of the fenestra with a dental polishing burr of different metals mainly steel gold pure lead and silver amalgam.

Experimental work carried out by the author and several of his associates at the Harvard Medical School, Boston on rhesus monkeys is briefly discussed. A different technique was employed on the animals and one ear on each was used as a control. On a number of animals the edges of the fenestra were burmished with the burrs of different types in which the burrs from pure lead were used and in these 3 ears there was no closure of a newly formed fenestra. Further control studies are being repeated on monkeys with the use of pure lead burrs, and the results are awaited.

On the basis of the histologic evidence obtained in burmishing the edges of all of the fenestra that he makes with the pure lead burr and hopes now that he has reached some successful technique that will make the fenestra remain permanently patent and therefore result in successful improvement in the hearing of all carefully selected cases. The steps

of the fenestra in the left ear. The fenestra non-ovalis is described.

In a third present, numerous quotations from the full text of papers are included, numerous histologic slides showing the histologic changes occurring with the closure by osteogenesis of the fenestra.

WILLIAM A. ANGELO, M.D.

Osteogenic following Fenestration of the Vestibular Labyrinth of the Rhesus Monkeys: A Controlled Experimental Study. JAMES LAWRENCE, JR., M.D., and LEONARD A. SCHALL, M.D., Boston, W. J. Lippincott Co., 1941, 46 p., \$2.50.

Through the courtesy of LeRoy A. Schall in the Department of Histology at the Harvard University Medical School, Boston, Lempert outlined the method of research in osteogenesis of the postoperative event of osteogenic closure of a fenestra non-ovalis in the vestibular labyrinth of the rhesus monkey.

All operations were performed by Meltzer in the experimental department which was performed by Lempert and Meltzer. The tissues were prepared in the Massachusetts General Hospital, and in the Lempert Laboratory and in the direction of Dorothy Wolff.

The investigation included three separate phases. Phase 1 was a study of the three individual histologic layers of the freshly cut bony rim of the fenestra of the rhesus monkey to determine the part played in osteogenic closure of the fenestra in phase 2 attempts were made to prevent osteogenesis in all three histologic layers by the use of various materials locally the histologic structure was studied in phase 3 attempts were made to prevent the closure of the fenestra.

In performing the experimental fenestration in the middle ear, the control of the peripheral endolymphatic space was studied.

The experiment was limited to a study of how osteogenesis replaced the freshly cut bony wall of the fenestra and the effect of the peripheral endolymphatic space.

The perimeter of the fenestral gap was not closed with cement, as it removed any doubt of the validity of the results. The results of the experiment are considered in the explanation and interpretation of the results of histologic observations.

In experiment 2 and 3 in which special experimental factors were introduced in an attempt to prevent osteogenesis in the right ear of the monkey, the left ear was operated on with the same technique as the right ear. In the right ear, the left ear was the experimental (control) ear used. In the right ear of each monkey was a control experimental ear, while the left ear was a control ear in monkey 3. In experiment

3) in which the reverse was the case. In all cases both ears were operated on at the same time.

With such controlled experimentation it is possible in the evaluation of the end result to eliminate error resulting from the fact that the control ear is influenced by biological factors influencing osteogenesis in the experimental monkey was unknown.

Experiment 1. In this first series of 13 monkeys (26 ears) the endosteum was left intact in the right ear and removed in the left ear. This was to determine whether the leaving or the removing of the endosteum made any difference in the end result. The results were given as day to day results and by the tenth day regeneration was complete with complete closure of the fenestra. Although early stages of fibrosis and regeneration were more rapid in the right ear on the side on which the endosteum had been left intact later stages showed complete regeneration on both sides with no distinguishing difference.

Experiment 2. Sixteen monkeys (32 ears) were used. In this experiment attempts were made to accelerate the histologic elements responsible for osteogenesis by burning the freshly cut rim of the fenestra in the right ear with various metal tips, a medicament and with an electrocoagulating current. The results showed that burning with 22 carat gold did not prevent bone regeneration, nor did burning with silver. Burning with silver amalgam retarded but did not prevent bone regeneration. Burning with a per cent aqueous silver nitrate solution retarded but did not prevent regeneration of bone nor did burning with stainless steel. Burning with electrocoagulating current had about the same results. Burning with pure lead prevented bone regeneration in the fenestra after 6 months and 25 days in the only 2 monkeys in whose cases the experimental fenestra was burned with pure lead. The control fenestra of these 2 monkeys were completely repaired by new bone.

Experiment 3. In the right ear of monkey A, the entire external semicircular canal was fenestrated. In the left ear a small fenestra was made in the external semicircular canal. The results showed regeneration to be complete in both ears. It was revealed that the length of fenestra seems to have bearing on ultimate regeneration of bone.

Experiment 4. Six monkeys (12 ears) were used. A cartilage stopple was placed in the fenestra of the experimental ear and over this a flap was placed in the opposite or control ear. The flap was placed over the fenestra but no stopple was used. Examination of the experimental ears showed that after 3 months the stopple was firmly anchored by new bone. The flap was not below the level of the stopple and no new bone was also invading the cartilage. Regeneration did not occur where the stopple fitted firmly to the edge of the fenestra. Thus the experiment showed that regeneration did not occur where the cartilage stopple fitted firmly against the cut edge of the capsule.

Experiment 5. Five monkeys (10 ears) were used. A film was inserted into the fenestra of the

penmental ear while in the control ear either a different kind of fibrin film or the skin flap alone was used. The results showed that fibrin film does prevent regeneration.

In summary the authors note that their results show only one hopeful conclusion viz that the burnishing of the edge of the fenestra with pure lead may be the means of keeping the fenestra from closing through osteogenesis.

The article includes histologic photomicrographs of specimens and tables showing the results in each experiment.

WILLIAM A. ASHROON, M.D.

Revision of the Fenestration Operation PHILIP E. MELTZER Arch Otol. Chic. 1947 46 528

The author mentions the fact that this subject has been little discussed in recent literature and that now otologists are having the opportunity of reviewing statistical reports of the end results from the fenestration operations. It now becomes apparent that there is a definite need for such a discussion. It is generally agreed among experienced surgeons that when cases are well selected a large majority of the patients will have the hearing improved to the practical level in consequence of the fenestration operation. This improvement occurs usually within 3 to 6 weeks. The percentage of cases in which hearing is so improved varies from 70 to as high as 90 per cent. However, in spite of the actual percentage of early good results ultimate failures are of such frequency that the question of revision is of major importance.

Accidents excluded the causes of postoperative failure in order of their importance are osteogenesis fibrosis, and labyrinthitis. The effect of the labyrinthitis varies with the severity of the condition mild cases result in very little damage to the hearing while severe cases have total loss of hearing.

Fibrosis as a cause of failure is hard to evaluate as, no matter how careful an operator may be, a film of blood elements will accumulate under the flap with resulting fibrotic tissue hindering down the flap to the bony capsule thus causing a decrease in hearing. The fibrous tissue may be minimal or quite extensive, even growing into the window and partly into the space containing the perilymph.

The most important cause of closure is osteogenesis in which new bone may completely or partially replace any connective tissue matrix. This may occur rapidly or slowly or may pile up in a large growth at the site of the fenestra. It may completely or only partially close the fenestra and in some cases the new bone is easily distinguishable in the first year or two but later on it becomes indistinguishable from the surrounding bone.

It is possible for any combination of these causes to take place to a greater or lesser degree.

As a failure may occur after the operation, it causes anxious waiting on the part of the patient and surgeon following the operation. Many patients will be disappointed and the results are variable dependent on constitutional factors beyond one a con-

trol. Some surgeons doing this operation have not obtained a high percentage of success and to them revision is important, and they would like to know when and under what circumstances reoperation is a reasonable undertaking.

Suitability for the selection of patients for revision would be determined after a complete study has been made of the record of the patient, including preoperative audiograms review of what occurred at the original operation and of the events that occurred postoperatively.

Assuming that the operation was carried out perfectly the fenestra was well made and of adequate size with no endosteal shreds and bone chips remaining the author offers the following opinion as to when revision should or should not be done.

When not to revise (1) a revision should not be done when a patient fails to get any improvement of hearing following the operation (2) it should not be done in a patient whose hearing recedes after he has obtained a limited improvement only and has never reached a practical level at any time postoperatively (3) revision should not be done in a patient whose threshold is improved in the lower frequencies but not to the practical level in the important speech frequencies (4) it is unwise to reoperate on a patient who had a good improvement and then rapidly lost it within a matter of 3 to 6 weeks especially if the hearing has receded below the preoperative level. This usually means fibrosis.

When to revise (1) a revision may be undertaken in any case in which a fenestra was made that was possibly too small. In this type of case the patient may lose his improvement rather rapidly within 6 to 8 weeks (2) if the hearing improvement remains for 6 to 8 weeks and is then rapidly lost and one has a feeling that a fragment of bone might have made its way into the window or that possibly a spicule of bone was attached to the canal wall membrane one is justified in revising sooner than usual provided the cavity is clean and well epidermized.

When one is contemplating a revision in some cases vestibular tests may afford valuable information as the fistula response is excellent in a fenestra that has remained patent but is negative if the fistula has closed.

It is much better to wait for all inflammatory reaction to subside. The best time for revision is usually from 6 to 8 months after it has become evident clinically that the fenestra has closed.

If the cartilage stopple technique was employed the following observations may help to guide one as to the proper time for revision (1) when a cartilage stopple is well fitted and firmly inserted into the fenestra the result may be that there is no improvement of hearing (The reason is that under this condition the stopple is immobile, being too tight and sound cannot be transmitted through the fenestra. In such cases, in which the hearing remains practically the same a revision may be undertaken within 4 to 6 months or earlier depending on the appearance of the cavity) (2) when a stopple is well fitted

but yet not too firmly and the learning is good for the ear and then it will recede to the pre-operative level and revision may be undertaken 4 to 6 months later. Revision may be undertaken in cases with partial improvement never reaching the pre-operative level of hearing at 6 months later.

In some cases that presumably were well selected for revision the findings at operation may be so different from those expected that prudence justifies the immediate replacement of the flap. If during revision it seems difficult to expose the perilymphatic space and therefore that further instrumentation will result in damage of the labyrinth the operation should be stopped. On elevation of the bone membrane and the tissue extending into the middle ear the perilymphatic space may be filled with a small amount of fat. Attempted removal of this material will usually cause evulsion of the membrane labyrinth with irreplaceable damage and if this material should be discovered the ear should be left alone.

Of the relevant factors from the history of the case to be taken into consideration in considering revision.

A case is not a good subject for revision if it is malignant, soundness determined from the history.

If the bone wall of the middle ear at operation was found to be usually broken with great probability of revision. This will be true when the fenestra is revised.

If the bone wall was fractured at operation, particularly that part nearest the middle ear membrane it may be that a fragment has remained attached. This will have resulted in a foreign body. In such cases revision is indicated.

If labyrinthitis occurred, the patient after the operation has usually been contraindicated. The leveling of the improvement of hearing when it was noted and when the hearing began to decline will probably lead to the diagnosis of early labyrinthitis and the need for reoperation.

A case in which rapid loss of hearing has occurred since the first operation frequently allows modification of the patient's usual unsatisfactory operation.

Patients who have been postoperatively satisfied but reach a pre-operative level at a later time are satisfactory for reoperation with the exception of those patients who have had a long history of inserted.

WILLIAM A. A. M. M.D.

Medical and Surgical Care of the Patient Selected for Fenestration of the Labyrinth. J. M. D. A. J. Otolaryngology 1937 4: 551

The author states that the hearing for normal speech can be restored in a large percentage of patients with the ear selected for fenestration. If the patient has a middle ear disease, it is essential that it be removed. If failures occur, the patients become better. The failures have been more numerous in the past but have been more numerous in the past.

of dizziness. The author believes that the ear and failures and the number of disappointed patients may be markedly decreased if the success of the fenestration operation are thoroughly trained and able to carry out the operation with perfect technique. However many men who have not as yet had the necessary experience are performing the operation and their patients make up a large number of failures.

There are three primary causes of failure: (1) diagnosis and selection of cases, (2) fibrous reaction in the vestibule from hemorrhage, the entrance of foreign material or damage of the vestibular nerve, and (3) closure of the fenestra.

It is the author's opinion that closure of the fenestra is due not merely to the natural tendency of bone to regenerate but to bone dust, endosteal tags or spicules of bone left in the fenestra or on the flap covering it or to an inflammatory reaction. The author provides the stimulus necessary for bone regeneration. He believes therefore that the fault comes with the operator as a clean fenestra covered by a clean and healthy flap will not close in the absence of a stimulative inflammatory reaction.

Every surgeon who undertakes this work should keep a careful record of every case not only the history of the patient but a record of the operation, procedures and of the postoperative course. If it does this and failure occurs, he can look back and find the cause and similar failures in other patients may be obviated.

Aside from the technical procedure of the operation itself, there are other details associated with the medical and surgical care which are important. The person who is to undergo the operation should be in good condition both physically and mentally. Preoperatively special attention should be paid to the possibility of active nasal allergy as the author believes that failure resulted in at least 2 of his cases because of active nasal allergy causing inflammation of the ear which in turn stimulated bone regeneration. Physiologic instability also must be reckoned with as a psychic shock from having one's fear of the operation may be just as severe as the shock of failure. The author has seen a patient in whom active manifestations of dementia praecox developed after a successful fenestration.

The author states that practically all of the operations can be done under a local anesthetic and that the patient must be given a careful explanation of what he may feel and hear during the operation that he will not become unduly upset.

The author's ideas concerning preoperative preparation and the surgical preparation for the operation are presented. He believes that a septic solution should be kept out of the ear canal because they may promote inflammation but it is simply filling the ear canal with a 5 percent alcohol for 30 minutes is effective and does not cause discomfort. The packing used in the cavity at the conclusion of the operation should be nonirritating and should be a good structure and paraffin gauze is satisfactory.

It should not be packed too tightly as it may cause pain, and pain indicates the presence of some inflammatory reaction. Patients sit up on the day of operation if possible and get out of bed on the day following. The author has noticed if this is done the labyrinth becomes more quickly adjusted.

Postoperative care of the cavity is very important and some failures can be traced to poor care and discontinuation of treatment before the cavity has become completely healed. The author mentions many minor surgical principles but he believes that all surgical procedures whether minor or major should be carried out with extreme care in order that satisfactory results may be obtained in all cases.

WILLIAM A. ANDROO, M.D.

Training of the Surgeon and Selection of the Patient for the Fenestration Operation J H MAXWELL, *Arch Otolaryngol* 1947 46 539.

Apparently the technical training of most surgeons performing the Lempert operation has been fairly adequate from the standpoint of anatomic dissection. It should not be forgotten however that the operation is something more than an anatomic dissection to be performed on the living patient. It is a major surgical operation involving vital structures and requiring for its satisfactory performance a high degree of technical skill. The prerequisite training of the surgeon who is interested in the treatment of otosclerosis should include, first of all, a wide background of diagnostic and surgical experience in the general field of otology. After he has studied the entire problem of deafness in all its phases this well disciplined otologist is ready to prepare himself to perform the fenestration operation. In the final preparation it is generally advisable for him to go to an institution such as Lempert's laboratory where he can perform the operation on cadavers under supervision and also have many opportunities to observe experienced surgeons perform the operation. It is most important for the beginner to study the skills by which experienced surgeons surmount the various technical difficulties of the procedure.

It is readily admitted that there is considerable latitude in the selection of patients suitable for the fenestration operation. Any attempt to draft hard and fast rules fixing the degree of handicap the exact positions of the air conduction and bone conduction curves on the audiograms or the age limits in regard to this operation is entirely beyond the author's province and capability. Certain principles, however must be held inviolable and after careful attention has been given them, the final decision must be based on clinical experience moderated by common sense.

In the first place it is obviously necessary to make a reasonably accurate diagnosis of the hearing impairment of which the patient complains. The conductive deafness which may lead to a diagnosis of clinical otosclerosis must not be determined from the audiogram alone or from the audiogram in addition to a casual and superficial objective examina-

tion. Nasopharyngeal examination and otoscopy to exclude tubotympanitis or adhesive otitis as the cause of impairment of hearing are time consuming but are important parts of the examination.

It is highly desirable to have a series of three or four audiograms taken several days apart in an effort to gain accurate information regarding the acuity of the patient's hearing of pure tones. The hearing should then be tested routinely with tuning forks since they give valuable information in the vast majority of cases. The candidate for fenestration should have a strongly negative Rinne test and a positive Schwabach test with the C 3 (1024 double vibrations per second) tuning fork, and with few exceptions he should lateralize sound in the Weber test to the worse ear when the C 3 and C 4 forks are used. The chief value of the tuning fork test is to check the audiogram which on many occasions is found to be inaccurate in spite of frequent calibration of the audiometer.

In addition to the tuning fork tests and pure tone audiometry, the testing of speech reception is most important, for it is obvious that the patient's greatest interest is in his ability to hear speech. It is to be hoped that the time will soon come when all reported results of the fenestration operation will show the preoperative and postoperative thresholds of speech reception. The degree of the patient's handicap and the success of the operation can be shown to much better advantage by this means.

The author believes that no patient is suitable for the fenestration operation unless it can be shown by accepted tests that there is sufficient cochlear function to permit the hearing to be restored to a serviceable and practicable level through the successful by-passing of the obstructive element.

Handicapped persons will grasp at straws. The patient with profound deafness is willing to try almost anything that offers even a faint ray of hope that his affliction will be ameliorated. Many times such a patient will beg the surgeon to do the fenestration operation even though he has been told that he is unsuitable. The performance of the fenestration operation as a surgical experiment is a violation of the ethical concepts of the profession. As a surgeon, one does not have surgical commodities to sell. One has opinions and advice to offer. If a surgeon feels that the operation should be done he should so advise the patient. If according to available and accepted hearing tests a patient is classified as unsuitable for the fenestration operation, the operation should not be recommended. This patient should be apprised of his condition and given advice and assistance in regard to rehabilitation through speech reading and the use of a hearing aid.

JOHN F. DELP, M.D.

General Correlation MARVIN F. JONES, *Arch Otolaryngol*, 1947 46 544.

There is a definite and too great element of error in the present methods of arriving at a diagnosis of otosclerosis, which precludes dogmatism.

and other parts of the brain. Although much anatomical and histological investigation has been carried out, the exact pathways in many instances are not known. It is this lack of detailed knowledge which renders the information derived from the vestibular tests of questionable value in diagnosis.

Dizziness or vertigo may result from stimulation or disease of any of the structures concerned in the maintenance of balance. We therefore may have ocular vertigo, central vertigo or labyrinthine vertigo. Frequently it is difficult to distinguish between the various causes. We must rely upon the history and the description of the vertigo and upon the associated signs and symptoms.

If the cause of the dizziness or vertigo is within the labyrinth, there is frequently associated evidence of disease of the cochlear mechanism as instanced by the presence of deafness and tinnitus. The vestibular tests may or may not be abnormal. There may be spontaneous or positional nystagmus.

Vestibular tests for the semicircular canals include the rotation, the caloric, and the galvanic tests but by far the most commonly used test is the caloric test. It has the advantage over the rotation test of stimulating only one labyrinth at a time. It has an advantage over the galvanic test in that it stimulates only the end organ and not the vestibular nerve.

The cold caloric test is used much more frequently than is the hot probably because it is difficult to arrange hot stimulation so that it will be effective and yet not be painful to the patient.

For a cold water test, 2 or 3 c.c. of ice water introduced by a syringe under vision and kept in contact with the ear drum for 20 seconds is a very practical ward or office test. The nystagmus if timed from the onset of stimulation lasts for 2 or 2½ minutes.

A simple and dependable method of carrying out the vestibular caloric test is to use a Dundas-Grant coiled tube for cold air. The air is cooled by pouring ethyl chloride on the covering cloth mesh. The advantage of this method is that it is simple to carry out and can be done in any hospital ward or doctor's office. The cold air makes the test safe even when there is a perforation in the drum.

A clinical vestibular test must be as all informative as possible and yet it should be as simple as possible. Any increased complexity in the test must give dependable information which is of clinical value before it is accepted. If we allow the test to become too complicated or if we attempt to conclude too much from a test, it will fall into disuse and disrepute.

JOHN F. DELPH, M.D.

Pathology of Vertigo Arising from the Peripheral Vestibular Apparatus. J. R. LINDSAY. *Ann. Otol. Rhinol.* 1947, 56, 541.

Vertigo is a common symptom of a disturbance of either the peripheral labyrinth or its central nervous pathways.

In disease of the central nervous system such as encephalitis, abscess, tumor and multiple sclerosis, the symptoms result from direct involvement of

vestibular nuclei or pathways or from pressure. Vertigo following head injury with concussion probably is central in origin if unaccompanied by auditory disturbance.

Vertigo without deafness or tinnitus occurs frequently as a toxic manifestation in the course of some respiratory and gastrointestinal infections. It may occur in cerebral arteriosclerosis and hypertension and also in hypotension and during the menopause. The localization is indefinite but the absence of auditory symptoms suggests that it is central and the pathologic disturbance of a mild and reversible character.

Vertigo can be localized to the peripheral labyrinth or eighth nerve when the symptom is associated with deafness and tinnitus. The most frequent cause in the past has been a labyrinthitis, due to extension of inflammatory disease in the temporal bone, or to meningitis. The pathologic process in the inner ear in various types of labyrinthitis, tumor and fractures of the temporal bone have been described in standard texts.

A disturbance of the peripheral labyrinth may also occur from several other causes. A nonsuppurative otitis media may produce vertigo which in some cases is relieved promptly by inflation or removal of serous fluid. An attack of extrinsic allergy may in rare cases cause vertigo. The nature of the inner ear disturbance in these is indefinite. Certain infections, particularly virus diseases, may affect the inner ear and produce rapid, profound loss of hearing and in occasional cases, vertigo and some loss of vestibular function. Precise information as to the pathologic process in the inner ear is lacking since material for pathologic study is rarely available.

A sudden onset in previously healthy ears of tinnitus, deafness and vertigo which leave a profound and permanent impairment of function if occurring in middle life or later is considered to be due to a vascular accident in the labyrinth. A similar episode sometimes occurs before middle age and in these cases it may be impossible to differentiate the condition from an acute toxic process. A toxic disturbance affects auditory function primarily however and may not impair vestibular function. Precise pathologic information in this type of labyrinthine lesion is not available. A fibrous labyrinthitis occurring in the late stages of leukemia has been described and is thought to be the result of hemorrhage in the labyrinth.

The clinical condition now called Meniere's disease, which is characterized by recurring attacks of vertigo with fluctuating tinnitus and deafness is now known to be associated with a hydrops of the labyrinth. This type of hydrops is distinguishable from that which sometimes occurs in inflammatory inner ear disease since in the former there are no inflammatory changes in the perilymphatic spaces and degeneration of the peripheral cochlear neuron is usually absent. The term idiopathic labyrinthine hydrops is customarily applied. The etiology is not known.

JOHN R. LINDSAY, M.D.

PHARYNX

Congenital Abnormalities of the Pillars of the Fauces and the Action of the Posterior Pillars and Nasopharyngeal Valve during Speech
MICHAEL C. OLDFIELD and L. P. J. MACNAUGHTAN
J. Laryngol. 1946 6 594

Observations were made on patients with several types of congenital defects of the pharyngeal muscles.

On the basis of these observations the author presents the thesis that the palatopharyngeus muscle and the thyropharyngeus muscle previously thought to be parts of the same muscle are independent, both on the basis of development and function. The palatopharyngeus muscle, arising from the posterior pharyngeal wall and entering the soft palate, encircles the pharynx like a horseshoe-shaped sphincter and gives rise to the horizontal ridge on the posterior pharyngeal wall known as Passavant's ridge. The thyropharyngeus muscle, arising below from the posterior margin of the thyroid cartilage and pharyngeal sphenoid and passing upward on the lateral wall of the pharynx passes medially to the palate and forms the posterior pillars. The action is to bring the lateral pharyngeal walls and pillars medially. The posterior pillars play a subsidiary but important role in closing off the nasopharynx. One patient with congenital absence of the left posterior pillar was observed to have a nasal quality to his voice because of inadequate closure. The uvula serves no function in the closing of the nasopharyngeal isthmus.

JOHN R. LODGE, M.D.

NECK

Clinical Significance of Malignant Neoplasms of the Thyroid Gland WALTER F. ROCKES, JR., SAMUEL P. ASHBY, JR., and ROBERT H. WILLIAMS.
England J. M. 1947 37 569.

Of 544 918 patients admitted to the Boston City Hospital, the Johns Hopkins Hospital, and the Massachusetts General Hospital, there were 322 with goiters and 64 with a histologic diagnosis of malignant neoplasm of the thyroid gland. Other investigators report a much higher incidence: one has found 17.1 per cent malignancy in toxic nodular goiters and 7.3 per cent in all goiters. In a series of routine autopsies in a region of endemic goiter 1 per cent of thyroid carcinoma was found, whereas in a nonendemic area, only 0.1 per cent of the autopsies revealed cancer of the thyroid.

Of the 64 patients with cancer of the thyroid in the present study 76 per cent were women, 3 males and 22 females were under the age of 50. The age incidence increased regularly up to the seventh decade in 28 per cent of the cases the condition occurred in the seventh decade, in 21 per cent, the sixth decade, and in 18 per cent, the fifth decade.

The principal symptom was enlargement of the neck (86 per cent); next in frequency were hoarseness (18.7 per cent), dyspnea (18.7 per cent), dysphagia (14 per cent), bone pain from metastases (12.3

per cent), nervousness (10.9 per cent) and cough (9.4 per cent). No patient had hypothyroidism; 5 of the 64 patients had hyperthyroidism, and these 5 represented 0.38 per cent of all the cases admitted for hyperthyroidism. Physical signs were a palpable mass in the neck (98 per cent), the masses were nodular in contour (73.4 per cent) and in only 7.8 per cent were there multiple nodules. Enlargement of the cervical glands was found in 23.4 per cent, and of the supraclavicular glands in 7.8 per cent of the patients.

The degree of malignancy was classified as high in 36 per cent, moderate in 50 per cent, and low in 14 per cent of the patients. Of those in whom the condition was classified as highly malignant 70 per cent were dead in 1 to 5 years after operation and less than a third of the survivors were free of recurrence of those with moderately malignant growths, 25 per cent were dead, 7 per cent were living with recurrences 45 per cent were without recurrence and the remainder could not be traced. There were no known deaths in the low malignancy group but about one third of the patients had recurrence.

In order to arrive at a judgment concerning the indications for prophylactic removal of thyroid nodules an analysis was made of the complications resulting from operations on 431 patients with nontoxic goiter. Fifteen per cent of the patients suffered from one or more operative complications and the mortality was 1.16 per cent. 13 patients had vocal cord paralysis.

Since malignancy is most frequently associated with single nodules or masses, prophylactic surgery must be considered, especially in young people in nonendemic areas since in these areas nonmalignant nodules are rarely found in patients under the age of 30. Multinodular glands are rarely the site of cancer. Certain signs in glands with one or more nodules, such as increase in size and in firmness especially with fixation to surrounding tissues, were considered as indications for removal.

The authors do not approve of removal of nodular or diffuse goiter to prevent later development of thyrotoxicosis.

CLINTON H. THURMAN, M.D.

Carcinoma of the Thyroid J. M. GRAMAM and R. McWHIRTER. *Proc. R. Soc. M. Lond.*, 1947 40 669.

One hundred and forty-four unselected cases of carcinoma of the thyroid are reported from an area in which simple goiter is not endemic but occurs only sporadically. The sex incidence was 1 male to 3.6 females. (The simple goiter ratio is 1 male to 9 females.) The average age was 50.75 years with a range from 18 to 83 years.

The diagnosis of malignant disease was confirmed by histological examination in 97 of the cases. In the remaining 47 cases it was made on clinical grounds alone. All sections were reclassified by one pathologist as follows: adenocarcinoma, 23 per cent; papillary adenocarcinoma, 16 per cent; and undifferentiated carcinoma, 61 per cent.

In 34 cases (23%) there was a history of previous "goiter." Three of the tumors had their origin in aberrant thyroid tissue, 2 in a lateral aberrant thyroid and 1 in a lingual thyroid.

Differential diagnosis is a problem in the early stage. The appearance of a nodular goiter in a patient approaching middle age, recent increase in size, or alteration in consistency or outline should be regarded with suspicion. Fixation of the swelling to the trachea while the thyroid still moves freely on swallowing is one of the earliest signs to appear. Forward displacement of the trachea with antero-posterior narrowing of the lumen is much more suggestive of cancer than of simple goiter. The presence of extensive calcification does not exclude cancer. An analysis of the factors affecting the survival rate is difficult in this series for three reasons:

1. The survey is not limited to early operable cases but includes all cases referred to a large general hospital.

2. The series contains a high proportion of undifferentiated carcinomas (61%). These grow rapidly and are often inoperable. 35 per cent of the patients died within a month and 50 per cent were dead within 4 months of the time they first came to the hospital.

3. One third of the cases were not histologically proved to be carcinoma.

Twenty-nine patients were operable. Seven were treated by complete thyroidectomy and the remainder by subtotal thyroidectomy. In 18 cases postoperative x-ray therapy was also given. The 5 year survival rate was 73 per cent.

Among the 108 inoperable patients the 5 year survival rate was 16 per cent. Eighty-four of these

patients had no distant metastases and of these 30 were given x-ray treatment which could be considered adequate. Of the last, 29 per cent were alive at the end of 5 years.

The results obtained as compared with the histologic type of the tumor are as follows: 18 patients with adenocarcinoma—46 per cent alive at the end of 5 years; 13 patients with papillary adenocarcinoma—40 per cent alive at the end of 5 years; and 48 patients with undifferentiated carcinoma—14 per cent alive at the end of 5 years.

As no patient treated by surgery alone survived for 5 years the results must be attributed to x-ray treatment.

An analysis of the radiosensitivity of the 3 histologic subdivisions is given as follows: adenocarcinoma—0 per cent radiosensitive; papillary adenocarcinoma—0 per cent radiosensitive; undifferentiated carcinoma—55 per cent radiosensitive; unknown type—50 per cent radiosensitive.

The criterion of radiosensitivity was a rapid diminution in size of the tumor. Survival rates were ignored for obvious reasons.

Another finding of some help in distinguishing the radiosensitive group was the average duration of the symptoms which was 6.3 months in the radiosensitive cases and 16 months in the radioresistant cases. It is believed that if a tumor is of the radiosensitive type, no attempt at surgical removal should be made because incomplete removal will almost certainly bring about dissemination of the cells (mostly to the lungs).

Operation is indicated only when there is a reasonable prospect of removing the tumor completely.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Encephalography with Small Amounts of Air
KRISTIAN KRISTIANSEN and ARVALD VOGT. *Ida radiol. Stockh.* 947 8 335.

The authors report on encephalographic studies of 100 consecutive patients treated on the neurological service of the Rikshospitalet Oslo. A very small amount of air not exceeding 15 c.c. was used. The usual technique of the authors consisted of removing 4 c.c. of cerebrospinal fluid at 3 different times and injecting 3 c.c. of air at 3 different times so as to use only 9 c.c. of air for the entire study. In 11 per cent of the patients, the ventricles were sufficiently filled for diagnostic purposes, but the degree of filling was incomplete in 73 per cent, and there was no filling in 16 per cent. These studies frequently had to be repeated 2, 3, 4 and 5 times, with a little more air each time, the maximum being 16 c.c. In 30 patients with gross intracranial lesions, good filling of the ventricles with such procedures was obtained in none. In 14 patients with clinical signs of increased intracranial pressure, good fillings were not obtained but 3 deaths were reported among them.

The advantage of causing less headache with such small amounts of air seems to be offset by the fact that the procedure often had to be repeated. The authors have not been satisfied with the procedure and are resorting now to a more adequate injection of air. However they continue to use from 15 to 20 c.c. in the first attempt and if the results are not satisfactory they use from 40 to 60 c.c. of air. They recommend that all encephalographies be performed with the help of fluoroscopy so as to control the amount of air that is required to give a satisfactory filling of the ventricular system.

GEORGE PERRET, M.D.

Carcinoma of the Pituitary Gland with Metastases to the Liver in a Case of Cushing's Syndrome
W. ELIAS FORST. *J. Path. Bact. Lond.* 947 59 37.

A 43 year old woman developed symptoms of the disease known as Cushing's syndrome was treated unsuccessfully by deep x ray therapy and later at operation was found to show no gross tumorous changes in the pituitary gland. Her symptoms progressed and she died 14 months after her first admission to the hospital. At autopsy she was found to have a tumor within the confines of the pituitary gland, which structure had been essentially completely destroyed by the tumor. The tumor is described as being chromophobe carcinoma. In many scattered foci throughout the liver there were small tumors of the same histologic nature as that found in the hypophysis, and in no other organ after extensive study was there found to be any such

metastases. The cells in both the liver and pituitary tumors were quite unlike those of carcinoma of the liver and the gross distribution of the hepatic lesions was not that of hepatic carcinoma. The clinical picture had been, from the beginning, one of primary pituitary dysfunction and not one of liver disease. For these reasons the author believes the case to be one of true metastasis of a carcinoma from its primary site in the pituitary gland to another organ. Such a pathologic situation is a rarity.

JOHN MAXIE, M.D.

Multiple Meningiomas (Meningiomas multiples)
RAMON CARRILLO, RAUL F. MATTEA and TORIBIO INCHAUSTI. *Rev. As. med. argent.* 947 6 56.

The authors report the results of their experience, and establish the accuracy of Cushing and Eberhardt's observation of the existence of 2 anatomico-clinical entities: (1) a clear case of multiple meningioma without any manifestation of von Recklinghausen's disease and (2) this disease complicated by multiple intracranial tumors. Embryologic experiments support this belief.

Multiple meningioma is rare, occurring in from 1 to 4 per cent of tumors of this type. Diagnosis difficult because of the many neurologic symptoms caused by more than one tumor: the ineffectual ventriculography, and the nonmalignant character of the tumors from the histological standpoint.

STEPHEN A. ZIEGLER, M.D.

Neurinomas of the Cerebellopontine Region. A Clinical Study of 160 Cases Including Operative Mortality and End Results. A Correction.
TORIBIO GONZALEZ REVILLA. *Bull. Johns H. Hosp.* 947 80: 54.

The second sentence in the fourth paragraph, left hand column, on page 133 of the February 1948 issue is not correct. The author's own words are as follows:

From all these observations originated Dandy's classical unilateral procedure introduced in 1934 and which is briefly summarized as follows: 1. small unilateral incision as used for Ménière's disease and 2. bone rongeur used as far laterally as possible without entry to the mastoid cells and anteriorly to the lateral sinus. 3. tapping of the posterior horn of a lateral ventricle through a previously placed occipital trephine in the opposite side. 4. evacuation of fluid from the cisterna magna and spinal canal. 5. excision of the outer cap of the cerebellum. 6. intracapsular evacuation of the solid contents and 7. careful painstaking dissection and removal of the capsule. This procedure has been almost universally adopted and the general trend of most neurosurgical clinics at present is to remove these tumors in toto according to the method evolved by Dandy after 20 many years of toil.

SPINAL CORD AND ITS COVERINGS

PERIPHERAL NERVES

Studies upon Spinal Cord Injuries. The Development of Automatic Micturition. JOHN MARTIN and LOYAL DAVIS. *Ann. Surg.*, 1947 126 472

In a study of the rehabilitative problems of the patient with a severe injury to the spinal cord the authors cite their experience with 471 such patients, seen and treated both in civilian and military practice. Injuries at all levels of the cord and cauda equina, both of the open and closed types, made up this large series of patients whose histories were carefully recorded. Many of these patients had been under the observation of the authors from the time of injury.

Urinary function in these patients appeared in one of the 5 following forms (1) early return to normal micturition (2) eventual return of partial voluntary control of micturition (3) involuntary dribbling of urine, or the frequent uncontrolled passage of very small amounts of urine (4) absolute retention (a less common situation), and (5) automatic or reflex micturition entirely free of any voluntary effort on the part of the patient. The early care of the bladder is of utmost importance to the future function of the bladder and therefore not only to the completeness of the patient's possible degree of rehabilitation but to the very preservation of his life. Such measures as intermittent catheterization, manual expression of the bladder, penile urethrostomy, suprapubic cystostomy, distention and overflow, and other such anphysiological and unsafe measures are to be condemned and avoided wherever possible. Even the exigencies of war do not excuse their use in most instances. Every effort must be made to effect the automatic emptying of the bladder for only under such conditions will the urinary tract remain as free of infection as is possible. The authors state that the effect on the patient's morale of a change for instance, from a suprapubic tube to automaticity is spectacular.

Automaticity was found to have developed in the authors' patients following a complete lesion at any level within the spinal cord or cauda equina. It developed in 14.3 per cent of the patients with cervical cord injuries, in 34 per cent of those with thoracic cord injuries and in 16.4 per cent of those with lumbosacral injuries. It seemed to appear earlier and with greater efficiency in the presence of lesions between the levels C-7 and Th 5. Severe altered reflex activity, sepsis from an infected bladder or bed sores, and general inanition may spell the termination of automatic micturition. Furthermore, automaticity will develop only when there is no mechanical bladder neck obstruction and when the sphincter is capable of reflex relaxation. For that reason resection of the bladder neck has been found to be a distinct aid in many patients. Extravesical stimuli are an aid but not a necessity to the development and maintenance of automatic micturition.

Nerve Lesions in Bone Injuries. HERBERT JOHN SEDDON. *J. Am. M. Ass.*, 1947 135 691

Even in his extensive personal experience Seddon feels that the prognosis may be very uncertain when nerve injury complicates a closed injury of certain long bones. He points out that while it is true that a large number of such injuries result in spontaneous recovery of the nerve operation may eventually become an absolute necessity and when the decision is finally made for surgical intervention the most favorable time for such treatment has already passed. On the other hand routine exploration is not justified.

The author has chosen to classify these injuries into three categories. In the familiar transient paralysis, neurapraxia, motor loss is usually complete, sensory loss is incomplete and the reaction of degeneration is absent. Recovery is as expected spontaneous. When neurotmesis exists there is complete disorganization of the nerve, even complete severance and recovery will come about only through surgical repair. In the event of axonotmesis, the Schwann tubes are preserved but the axons are ruptured and in such cases delayed but eventually spontaneous recovery will occur. The major problem therefore is to know which of these two latter types of injury is present in any particular bone nerve lesion.

When injury has been caused by a bony spike the lesion usually is well localized in the nerve but in many severe traction injuries the actual injury to the nerve may extend over many centimeters. The injury may be so severe and over such a great distance in such major traction injuries that, while anatomic continuity exists, intraneural scar formation reduces the lesion essentially to one of neurotmesis. Clinically there may be some difficulty in distinguishing between a traction lesion and a localized direct injury, but if the extent of the paralysis indicates that the lesion in the nerve exists proximal to the site of the fracture then only a traction type of injury can exist. In such a case the prognosis is grave as apparently nothing less than heroic surgical measures could offer any help.

Fractures of the shaft of the humerus most commonly involve the radial nerve and in such injuries compression or division of the nerve by a bony fragment is the rule.

Isolated axillary nerve injuries are usually due to traction and the prognosis is uncertain.

JOHN MARTIN M.D.

Experimental Research on Nerve Ligation (Recherches expérimentales sur les ligatures des nerfs). M. P. CHENILLEAU. *Bordeaux chir.*, 1947 No 2 p 60

The author using rabbits has recently shown the effects of ligating the free cut end of the central stump of a peripheral nerve such as might be done at the time of amputation of an extremity. He points out that older surgeons as Velpeau and Dupuytren

cautioned specifically against the inclusion of large nerve trunks in the neurovascular bundles at the time of amputation because of the severe pain or other "grave accidents" which might befall the patient after such treatment.

Quite on the contrary, Chenilleau has shown that he can prevent trophic ulcers in animals following the resection of 1.5 to 2 cm. of the sciatic nerve, and has seen evidence of painful neuromatous reaction after several months if at time of operation, he ligates the central stump approximately 1 cm. from its end. Control animals without such ligation have been studied together with those in which the nerves were ligated with catgut, and in others with a linen thread. Invariably the animals not treated by ligation suffered much more severe trophic ulcers than those ligated with catgut, and those ligated with linen had little or no trophic disturbance and were much better than the animals treated with catgut. Good photographs of the animals bear out these statements. The author believes that the linen thread obviates the formation of a neuroma locally and that a catgut ligature tends to do the same thing but that the local reaction produced by the catgut minimizes the otherwise good effect of the ligature. The linen, he feels, exerts a regulating and order-producing effect on the terminations of the severed neurones, and thus prevents the wild disorganization of the untreated nerve end. There is, likewise, clinical evidence at hand to support his findings in animals.

JOHN MARTIN, M.D.

Rate of Regeneration in Human Peripheral Nerves: Analysis of the Interval between Injury and Onset of Recovery SYDNEY BOWENLAND, *Arch. Year Psychiat. Chic.*, 1947 58: 25

There are two distinct events in the functional regeneration of a peripheral nerve: (a) the axon regenerates anatomically, and (b) the axon matures functionally after myelination and increase in diameter of the fiber. The second event follows the first and proceeds at a slower rate, but both slow up progressively as the axon tip moves farther from the cell body. Thus the initial rate is faster when the lesion is close to the parent neurons and slower when the lesion is farther distal.

When the nerve is not actually severed but there is a destruction of the axon from crushing or contraction of the nerve, the rate of functional maturation over the proximal portion of the nerve (arm and thigh) is in the vicinity of 3 mm. per day and slowly diminishes to approximately 0.5 mm. per day over the distal portion (hand and foot). When there is division and retreat the rate of functional maturation

is somewhat slower. The rate of regeneration is the resultant of (a) central forces provided by the cell body and (b) the peripheral resistance against which the central growth forces act. The rate in the initial stages of recovery is faster with high lesions, since these are closer to the parent neurons, while at the lower levels, the initial rate is slower because of the influence of the central forces of growth is weaker.

It is believed that repair is adversely affected by wound infection and scarring only when these factors add to the severity of the nerve lesion.

DORRIS ROSE, M.D.

SYMPATHETIC NERVES

Procaine Block of the Sympathetic Nerve in the Study of Intractable Pain and Circulatory Disorders. JAMES C. WINTER, *Surg. Clin. N. Am.*, 1947 7: 863

The diagnostic injection with procaine of various parts of the autonomic nervous system has led not only to accurate diagnosis and, in many instances, to the accurate prognosis to be expected from surgical treatment, but also has indicated the true anatomy and physiology of previously poorly understood pathways for the transmission of certain visceral sensory impulses. The usefulness of sympathetic block in testing for the effects of surgery in such diseases as Raynaud's syndrome, causalgia, and other intractable pain states is well recognized. Through such testing we have come to realize the value of sympathectomy at the proper levels for angina pectoris, the pain of aortic aneurysm, intractable pain of the gastrointestinal tract and the pancreatic and biliary tracts, painful osteoporosis, and certain types of painful amputation stumps. Such preoperative blocking of the sympathetics has been found to be of less prognostic value in thromboangiitis obliterans and arteriosclerosis. It is through the effectiveness of paravertebral block that surgeons have been able to develop methods of viscerosensory denervation which carry a minimal risk and do not disturb cutaneous sensation. For instance, it has been shown many times that the pain of angina pectoris can be obliterated by posterior rhizotomy on the first through the fourth thoracic nerves but the same control of pain can be obtained by resection of the upper three or four thoracic sympathetic ganglia.

Several excellent diagrams, typical of articles by this author demonstrate the techniques of sympathetic block as well as certain of the autonomic pathways in the diseases discussed.

JOHN MARTIN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Cystic Disease of the Breast: Human and Experimental B D PULLINGER. *Lancet* Lond., 1947
2 567

There are three outstanding questions concerning cystic disease of the breast. These are (1) the mode of origin (2) the cause and (3) the relation to cancer.

According to Cheate and Cutler (1941) 20 per cent of all mammary cancer begins in cystic breasts. This is an association and not necessarily a causal relationship.

Ovariectomized virgin young and mature female mice of two strains (R3 and C3H) were given single physiologic doses of two naturally occurring estrogens (estradiol and ketohydroxyestrin) in 400 microgram doses. (There are some data to indicate that the dose used was excessive even from the point of view of causing a pathological rather than a physiological response.) The response to the 400 microgram dosage was similar for both estrogens.

With the R3 mice some breast acini were ballooned out and became cystlike—a pathological adenosis with secretion and distention. Estrogens alone produced this change which according to previous knowledge should have required the combined action of estrogen, progesterone and probably a lactogen.

With C57 black mice a typical normal mammary gland response to both estrogens was obtained. It is clear from this that there is a strain difference in breast response to estrogen in mice. Two high mammary cancer incidence strains (C3H and Strong A) responded normally, e.g. there was no increase in cancer.

In the mouse with responsive inbred strains a peculiar reaction is found in every part of the gland. Hybrids of two strains (R3 which reacts vigorously and C57 black which reacts by duct outgrowth only) were tested and a part of each mamma reacted like one parent, part like the other, the proportion being about half and half. This dual response suggests that the localization of cystic response is hereditary. Mongrel mice showed comparable responses. There are apparently specially sensitive portions in the mammary epithelium. The distention in rodents appears to be passive due to rapid secretion of a milky fluid before which the walls of the ducts and acini appear to give way.

Cystic disease in the human being is a disease *sensu generis* and not a part of a cancer process. Geschickter (1945) believes the origin of cystic disease to be estrogen and progesterone imbalance. Ingley (1942) emphasized the individual difference in anatomical types of glands. The occurrence of localized cystic disease under the conditions of these mouse experiments strongly favors Ingley's interpretation of the origin of localized cystic disease. The assumption of a difference in reactivity of epithelial cells in

different parts of the duct and acinar system in both human beings and mice would resolve the divergent opinions.

Evidence of inheritance of cystic disease in human beings has not been collected. The decisive factor appears to be not merely an excess or imbalance of estrogen but an atypical response of mammary epithelium. This response predisposes to mammary cancer in mice when the cancer is activated by the milk tumor agent. Its relationship to clinical carcinogens has not been determined.

FRANK B. QUEEN, M.D.

Radical Mastectomy: Prognosis after Survival for 5 Years. ARTHUR B. MCGRAW. *Arch. Surg.* 1947 55
292

The close observation and study of the author's series of patients with cancer of the breast, especially of those who survived operation 5 years or more has in every way strengthened his conviction that a thoroughly radical operation is the only procedure at present giving such patients a good chance of long survival. He believes that such an operation should be undertaken whenever it can be performed with technical adequacy unless coexisting metastases are so advanced or widespread and the patient's expectancy of life is clearly so short as to make operation futile.

One hundred and seventy-seven patients (43 per cent of all cases) survived the 5 year period.

JOHN J. MALONEY, M.D.

TRACHEA LUNGS AND PLEURA

Bagasse Disease of the Lungs. DAVID V. LEMMON, WENDELL G. SCOTT, SHERWOOD MOORE and A. LOUIS KOVEN. *Radiology* 1947 49 556

Bagasse disease of the lung or bagassosis, is a pulmonary disorder brought about by inhalation of sugar cane after it has been crushed and the juice extracted. Only from 30 to 40 cases have been reported since it was first described in 1941 by Jamison and Hopkins.

The disease occurs only in people exposed to the inhalation of dry bagasse dust. This product is used in the manufacture of acoustical and thermal insulating building materials and in the production of refractory brick. The disease is restricted to communities which cut and process sugar cane (Louisiana or Cuba) manufacture building board (England) or make refractory brick (Missouri).

The symptoms and clinical course vary with the length of exposure and density of inhaled dust. About 2 months of exposure to the dust is necessary although the time varies from 3 weeks to 2 years. The disease is an acute febrile illness accompanied by extreme dyspnea, weakness, and a persistent cough with scanty mucoid sputum. The onset is in

idious. Cyanosis appears in only the most severe cases. The patients appear to have a severe bronchiolitis and pneumonia. Patients with long exposures are critically ill. In a series of 24 cases collected by Hunter there was a mortality of 83 per cent. However most of the patients who have had shorter exposures and lighter concentrations of the dust contract a less severe form of the disease which clears in from 2 to 6 months.

The fever usually ranges from 37 to 40 degrees and persists for 2 to 3 months. The pulse and respirations are increased. Percussion of the chest reveals a slight decrease in resonance. Breath sounds are normal and whispered voice may be increased. Moist crepitant rales are heard throughout both lungs. In severe cases the white blood cells may reach 16 to 20,000 with a shift to the left and an increased sedimentation rate. An eosinophilia (3.5-8%) is usually present. Blood chemistry and sputum cultures are negative.

The x ray findings are not characteristic and depend also on duration and concentration of exposure. In severe cases a fine punctate infiltration throughout both lungs is seen. These areas become nodular as they clear. Areas of early consolidation accompany the infiltration. The x ray changes seem to be reversible after a period of 3 months. In from 5 to 6 months the lung fields appear normal. Patients exposed to shorter and lighter concentrations show only a fine granular lace network of infiltration throughout both lungs which is heavier at the hilum in the left lower and middle lung fields.

Only 3 cases have been examined pathologically. They showed a fibroblastic reaction of the interstitial tissue with small needlelike spicules of an irregular foreign material (2 to 8 micra) imbedded in the pulmonary tissue. The large alveolar cells with foamy cytoplasm were more numerous. The pulmonary changes were those of an organic pneumoconiosis.

The etiology of bagassosis is obscure and it has never been reproduced in experimental animals. Whether the pathological reaction is due to fungi, bacteria, or a virus associated with the dust, or to an allergic response to the bagasse or its possible infectious agents or their products, or to some chemical or physical property of the dust, or any combination of these has not been determined.

There is no specific therapy the patients are treated symptomatically. Oxygen has afforded relief from dyspnea. Penicillin and "sulfa" drugs have had little effect.

Three case reports complete with roentgenograms are presented.

ROBERT R. BROWNE M.D.

The Pathogenesis of Bronchiectasis. TRACY B. MAILLORE *N England J M* 947 37 795

Five factors—chronic bronchial infection, congenital abnormalities of the bronchial tree, bronchostenosis, pulmonary telecystasis and pneumonitis or its sequelae, pulmonary fibrosis—are potential agents in the etiology of bronchiectasis. Of these, congeni-

tal cystic disease and bronchostenosis are comparatively uncommon.

Bronchial inflammation alone is rarely an effective factor, but in combination with atelectasis or pneumonitis it accounts for most of the characteristic features of the disease.

SAMUEL KATZ, M.D.

HEART AND PERICARDIUM

The Pathophysiology of the Cause of Death from Coronary Thrombosis. GORDON MURRAY *Am Surg* 1947 126 33

A condition of paradoxical systole has been demonstrated experimentally in the hearts of animals following coronary occlusion. This state is accompanied by a fall in the blood pressure and diminished cardiac output.

Following resection of the infarcted area in the heart, there is an improvement in the blood pressure and in cardiac output. The technique is described in detail.

It has been demonstrated that, compared with a control group of animals, the prospects of survival are 80 per cent. Operation was done on 25 animals.

It was suggested that the best treatment of acute coronary occlusion in the human being in selected cases might be immediate surgical operation. This would provide:

1. A better chance of survival from the effects of a severe and large infarct from a major occlusion.
2. A cure of the patient from an infarcted area of the heart which would eliminate the dangers of acute rupture, aneurysm, and subsequent rupture. It would remove all the effects of a coronary occlusion.

JOHN J. MALONEY M.D.

ESOPHAGUS AND MEDIASTINUM

Congenital Atresia of the Esophagus with Tracheoesophageal Fistula: A Report of 6 Cases. JOSEPH A. FERROULT, WILLIAM H. FLEMING, and THORBORN R. WEITAKER. *Arch Otolaryngol*, 947 46 668.

Prior to 1930 congenital atresia of the esophagus, with or without tracheoesophageal fistula, was uniformly fatal. There have been 37 successful surgical recoveries among 464 cases reported in the literature, consequently the mortality has been reduced to 74 per cent.

Vogt classified these defects as (1) complete agenesia or absence of the esophagus, (2) atresia without fistulas and (3) atresia with fistulas. In the latter group are (a) a fistula between the trachea and upper esophageal segment, (b) a fistula between the trachea and lower esophageal segment, and (c) a fistula between the trachea and both esophageal segments. The last type comprises 80 per cent of all atresias found at autopsy. Associated congenital anomalies are encountered in as many as 50 per cent of the cases.

A patient with esophageal atresia and tracheoesophageal fistula usually appears normal at birth ex-

cept for a slight increase in mucus in the mouth and throat. Physical examination may be normal, or moist rales may be audible particularly in the upper lobe of the right lung. When attempts are made to feed the child, there is difficulty in swallowing associated with choking dyspnea and cyanosis. The mucus reaccumulates and rales increase as saliva or feedings are aspirated. Air will be found in the stomach if a lower tracheoesophageal fistula is present.

A more definite diagnosis can be made if a catheter is passed and meets an obstruction 10 to 12 cm from the alveolar margins. A small amount of iodized oil can be instilled under fluoroscopic guidance. When necessary bronchoscopy may aid in diagnosis.

Unless there is surgical intervention the infants die of pneumonia and starvation. Exploratory thoracotomy is the only definite method of determining the possibility of direct anastomosis of esophageal segments. Any operative treatment is designed to prevent aspiration pneumonia to provide some means of feeding, and to prevent gastric contents from being regurgitated into the trachea. Whenever possible a direct anastomosis is carried out. If this is not feasible the tracheoesophageal fistula is ligated, the upper esophageal segment is exteriorized and a gastrostomy or esophagostomy is performed with subsequent construction of an anterior thoracic skin tube to re-establish continuity. Haight in one operative series, reported direct anastomosis was feasible in 70 per cent of the cases. The thin friable nature of the lower esophageal segment makes it extremely difficult to make a direct anastomosis.

Only 2 cases have been reported in which the continuity has been restored by an antethoracic esophagus. Surgery is well tolerated if it is performed early before starvation or pneumonia develops. Post operative periods are stormy with episodes of cyanosis, dyspnea, fever, dehydration and pulmonary complications.

The authors review the histories of 6 cases seen at the Mercy Hospital, Pittsburgh, Pennsylvania, all of which terminated fatally.

From the experience gained in these cases the authors learned that the primary diagnosis may be overlooked while treating the patient for the pulmonary complications. (2) the diagnosis may be confused with pyloric stenosis, (3) the diagnosis must be made early and surgical intervention be prompt to save these patients. (4) iodized oil instead of barium sulfate should be used for diagnostic purposes. (5)

closure of the fistula between the trachea and the lower esophagus is essential to prevent regurgitation of stomach contents into the trachea and (6) frequent aspirations of the pharynx will prevent spilling over from the obstructed upper segment of the esophagus.

ROBERT R. BIGELOW M.D.

Congenital Atresia and Tracheoesophageal Fistula: 4 Consecutive Cases of Successful Primary Esophageal Anastomosis WILLIAM P. LONG
MIXE, JR. *Arch Surg.* 1947 55 330.

Four consecutive patients with tracheoesophageal fistula and esophageal atresia have survived ligation of the fistula and primary anastomosis of the esophagus. They are now taking all feedings by mouth and are gaining weight satisfactorily. One of these patients weighed only 3 1/2 pounds at the time of operation. Certain features of the diagnosis, the operative technique, and the postoperative care are discussed. The importance of the early recognition of the condition by the attending physician is emphasized.

JOHN J. MALONEY M.D.

MISCELLANEOUS

Injuries of the Chest. BRIAN BLADES *J Am M Ass.* 1947 135 818.

The advances made in the management of wounds of the chest during the war have not been the result of technical improvements but have resulted from judicious timing and selection of surgical procedures.

The absolute necessity for whole blood in the treatment of shock, rather than plasma, and the danger of the excessive use of morphine in shocked patients have been definitely established.

In cases of fractured ribs control of thoracic pain by paravertebral injections of procaine hydrochloride should in great part, replace strapping of the chest. In traumatic wet lung, also paravertebral procaine hydrochloride block is of great value.

In cases of hemothorax early aspiration helps to effect complete re-expansion of the lung and conservation of cardiopulmonary function. In cases of clotted hemothorax or fibrothorax decortication of the lung has given brilliant results. This operation involves an open thoracotomy for the removal of the fluid and clot from the pleura, and excision of the fibrous corset of tissue which holds the lung in a collapsed position.

SAMUEL KAHN M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

A Case of Strangulated Internal Hernia at the Age of 91 in the Femoral Inguinal Region. JAMES A. ROSS and J. W. A. DE KWORTU. *Br J Surg* 1917 35 9

This is a report of a 91 year old woman who was admitted to the Royal Infirmary, Edinburgh, with intestinal obstruction. At operation a loop of small intestine was found to be lodged in the mouth of a peritoneal pouch which lay transversely in the right iliofemoral opening lying superiorly. The femoral wall below the pericardial region and represented the femoral inguinal region or loss of Bicus. The nature and morphology of this peritoneal space is described.

LEWIS W. (1918, M.D.)

Repair of Sliding Inguinal Hernia through the Abdominal (Larouque) Approach. LAROUQUE. *Ann Surg* 1917 35 20

Cognizance of the infrequent use of the abdominal approach in the treatment of sliding hernia motivated this review of the literature and description of the technique. The poor understanding of sliding hernia is illustrated by the low incidence variously reported as being from 1 to 3 per cent. The diagnosis is usually made after the sac is exposed or opened.

The literature indicates that the hernia is usually repaired through the inguinal approach. Among 501 collected cases, the mortality was 2.8 per cent. The death occurred when the colon was resected. Most authors call attention to the danger of injury to the blood supply or to the wall of the bowel when freeing the sac from the bowels. Attention is called to the fact that fixation of the bowel (sigmoid or cecum) to the wall of the sac is not caused by inflammatory adhesion but by normal fixation of the bowel to the peritoneal wall which has been pulled over some way, has descended to become a part of the wall of the hernial sac.

The first use of an opening into the abdomen above the inguinal repair to reduce this type of hernia was reported in 1907 by Fiaschi and many others have reported variations of the procedure since that time. Larouque in 1909 and in 1924 described the technique used and described in detail by the author.

The usual inguinal incision is made. The sac is exposed and dissected free from the cord, opened on its anterior surface, and the colon is thus exposed. Through the same skin incision the internal oblique and transversus abdominis muscles are opened 1 inch above the internal ring, care being taken to avoid the iliohypogastric nerve. The muscles are retracted and the peritoneum is opened transversely as is the overlying transverse fascia. The contents of the hernia can be visualized. They enter the internal ring from above. The colon and peritoneum are then

completely freed from the cord structures and are drawn back into the abdominal cavity when it becomes apparent that the anterolateral wall of the sac is the lateral leaf of the mesocolon. This peritoneum is then sutured after the excess is cut away. The resulting suture line closes the lateral leaf of the mesocolon. A run across the floor of the inguinal region to close the internal ring, and within the inferior margin of the peritoneal opening in the abdominal cavity. The transversalis fascia is then closed and the internal oblique and transversus abdominis are sutured. The inguinal canal may then be repaired in the usual manner.

FREDERICK C. HOWELL, M.D.

GASTROINTESTINAL TRACT

Acute Volvulus of the Stomach (Volvulus agilis de estomago). CARLOS SILVEIRA BRAGA and LUIZ V. M. TORRES. *Rev med Rosario* 1917 37 504

The authors report a fatal case of gastric volvulus in a 39 year old woman with old rheumatic heart disease. She complained for many years of a vague undetermined postprandial distress unrelieved by food intake. Suddenly she developed an epigastric nonirradiating pain almost immediately after supper and continuous emesis.

Röntgen examination of the stomach disclosed an obstruction at the level of the antrum. At operation it was found to be a gastric volvulus in a longitudinal axis with total occlusion of the pylorus and partial occlusion of the cardia.

A congenital defect with lack of peritoneal coalescence and the characteristics of a "roentertum communi" was found to be the basis for the volvulus.

WILLIAM F. RECKITT, M.D.

Carcinoma of the Esophagus and Cardiac End of the Stomach. LLOYD L. LEE. *Arch Surg* 1917 35 20

Four cases of total gastric resection by the trans-thoracic approach and a case of resection of the esophagus by the same approach are presented. Of the 6 patients, only 1 patient who had had a resection of the esophagus, was alive at the time the authors article was prepared. The cases illustrate many of the pitfalls that may be encountered in the surgery and after care as well as the discouraging high mortality despite the most careful preparation and long hours of meticulous surgery.

Controlled respiration anesthesia with cyclopropane and chemotherapy to control infection, are the recent adjuncts that have opened up this field of surgery. Phemister is credited with the observation that the trans-thoracic, transdiaphragmatic approach gives excellent access to the stomach. Kirschner discovered that the entire stomach could survive on the blood supply from the arteries at its

pyloric end alone. Garlock pointed out that if the gastrohepatic and gastrocolic ligaments and the left gastric artery were divided the stomach could be converted into a long muscular tube which when the diaphragm had been divided could be stretched almost to the top of the pleural cavity.

The author describes the manner of freeing the esophagus for complete removal of that organ the manner of making the anastomosis between the esophagus and either the stomach or jejunum and the sutures necessary between stomach and pleura to suspend the stomach high in the apex of the chest cavity.

The necessity for exploring a carcinoma of the stomach through an abdominal incision to determine the operability prior to making the transthoracic approach is described. It is also pointed out that the thoracic incision may be extended across the costal margin and upper abdomen when better access to the pyloric end of the stomach is mandatory. The necessity for correcting anemia, electrolyte imbalance and nutritional deficiencies is stressed.

FREDERICK C. HORNELL, M.D.

An Exceptional Indication for Gastric Resection (Un'una indicazione eccezionale alla resezion gastrica) ANTONIO ANZANI Arch Ital Med Exp 1947 13 284

The author refers to a case of habitual vomiting due to gastric hypotonia and dyskinesia associated with esophageal and cardiac (gastric) atony in an individual of asthenic habitus and impaired development who presented a grave picture of inanition.

The patient was operated upon November 3, 1945. Gastric resection was performed with a decrease of the symptoms which has persisted to date. The pathogenesis is discussed; it is related to the dystonia and dyskinesia of the esophagus, the cardia and the stomach and associated with intrinsic and extrinsic disturbances of innervation.

LEONARDO FRONZONI, M.D.

The Absorption of Iron after Gastric Resection (L'assorbimento del ferro nel gastro-resecati) ULIO COBRICCI and ALDO BOLLETTI Ann Ital Chir 1947 24 261

The authors have studied the condition of 15 patients following gastric resection (7 Hofmeister, Finsterer, 4 Reichel, Polya, 2 Moynihan, Lucinelli, 1 von Hacker) for periods ranging from 6 days to 5 years and 9 months.

About 65 per cent of the patients presented an erythrocytopenia which was grave in one case. The hemoglobin was below normal in all cases and varied from 50 to 78, a striking hypochlorhydria was noted in all cases.

The authors conclude that the anemia is proportional to the amount of stomach resected and is accompanied by a hypochlorhydria which is more or less striking—achlorhydria in some patients and in 1 histamine resistant. The relation of iron absorption to gastric acidity is not to be considered as

cause and effect. It may act indirectly in that digestive processes are altered by its diminution and thus absorption is more difficult.

Two hypotheses are offered:

1. The deficiency in these individuals of a particular factor contained in the mucosa of the stomach which is diminished or absent following gastric amputation. This factor must act either on the endogenous metabolism of the metal favoring the fixation and maintenance in the organism or by stimulating erythropoiesis. It does not seem to have any influence on the intestinal absorption of iron.

2. A grave alteration in the digestive processes through the new anatomicophysiological conditions.

LEONARDO FRONZONI, M.D.

Principles Governing Total Gastrectomy: A Report of 41 Cases. GEORGE T. JACK, CORDON MCNEER, and ROBERT J. BOONER. Arch Surg 1947 55 457

The abdominal surgeon has by necessity taken up total gastrectomy in his attack on cancer of the stomach. The purpose of the operation is curative but unfortunately in most cases the results are only palliative. Total gastrectomy means removal of both the pylorus and the cardia and on examination the removed portion will show a bit of the esophagus at one end and a part of the duodenum at the other. The first total gastrectomy was performed in 1884 by Connor and the first successful one by Schlatter in 1897.

The well planned total gastrectomy is both an excision of the entire stomach and a dissection en masse of the related lymph nodes. The greater omentum, the lymphatics and nodes along the greater curvature, the nodes of the left gastropancreatic fold, the juxta-cardiac nodes, the right gastropyloric nodes, the infropyloric and retropyloric nodes, the lymph nodes of the lesser curvature, the gastrohepatic and gastrosplenic ligament and the nodes along the celiac axis should also be removed. If necessary the spleen and the peritoneum of the lesser peritoneal sac may be included in the dissection.

The authors report 41 cases of total gastrectomy, 37 for cancer, 2 case for sarcoma and 3 cases for benign lesions. There were 12 females and 29 males with an average age of 54 years and 5 months.

Pain was the initial complaint in 20 patients, with anorexia, weakness, indigestion, vomiting, belching, dysphagia, nausea, loss of weight and rapid satiation as the original complaints in others. Seventy-five per cent of the patients had symptoms for a year or less. This is similar to the percentage reported in a collective review of 162 patients. The average duration of symptoms for a series treated by subtotal gastrectomy was 16 months.

The indications for total gastrectomy are (1) location of the lesion, (2) limits plastica (4 cases of the reported series), (3) lymphosarcoma, (4) malignant leiomyoma or leiomyosarcoma, (5) multiple polyps, and (6) gastric ulcer high on the lesser curvature.

Fluoroscopic examination of the stomach is the most important and easiest way to determine the

extent of invasion of the tumor. Esophagoscopy may be necessary to show the upward involvement of the cardia and esophagus. The flexible gastroscope can be of value when the x ray studies show freedom of the cardia.

Patients are hospitalized 5 days before surgery and put on a low residue high protein, forced diet, liquid if necessary. Medical evaluation of the cardi-

vascular status is obtained. Restoration of the hemoglobin, red cell count, and serum proteins is carried out. Gastric aspiration and lavage with one tenth normal hydrochloric acid are daily procedures. The patients are sent to the operating room with an indwelling nasal Levine tube in place.

Continuous spinal anesthesia is the authors' choice and penthal is given intravenously for restlessness and apprehension.

In only 1 case was transthoracic total gastrectomy performed as the subdiaphragmatic approach is preferred when the distal esophagus is not involved.

Gastrointestinal continuity was restored by esophagojejunostomy in all but 1 case in this case esophagoduodenostomy was done. The latter procedure with its increased tension and higher mortality has since been abandoned.

When the blood is ope ed careful widespread exploration is necessary to determine the operability. If the lesion is resectable the right gastric, the gastroduodenal and the right gastroepiploic vessels are ligated and the mentum is resected from also g the transverse colon. The duodenum is divided and incised with the Kerr Parker closure. The coronary ligament of the left lobe of the liver is cut and the remainder of the stomach mobilized. The authors prefer a long loop antecolic jejunal anastomosis. A 3 layer closure—an outer row of black silk mattress sutures and an inner continuous gut suture is used. Previously prepared diaphragmatic peritoneal flaps are sutured over the anastomosis and tension is released by suturing the jejunum to the diaphragm laterally. An indwelling Levine tube is placed in the distal jejunum for feeding purposes. In 83 per cent of the authors' cases a jejunojejunostomy was performed.

Transfusions, oxygen blow bottles, chemotherapy early ambulation early feeding through the Levine tube, parenteral fluids and supplemental vitamin therapy are essential in the postoperative treatment.

In the authors' series of 41 cases there were 13 operative deaths (31.7%). Causes of death were pulmonary complications in 6 cases, and cardiac failure and peritonitis in 3 cases each.

Of the nonfatal complications, atelectasis (6 cases) pneumonia (9 cases) abdominal fistula (8 cases) serious wound infections (6 cases) and postoperative hypoproteinemia (9 cases) were the most frequent.

Following total gastrectomy there is remarkably little alteration in nutrition. There is a disturbance of fat absorption, an increased loss of fecal nitrogen, a more rapid absorption of glucose and often a hypoproteinememia. Only 3 patients had moder-

ate anemia of the normochromic normocytic type. Nearly all of the patients were unable to gain weight.

On December 1, 1945 there were 11 living patients in this series. 7 of the patients who had had cancer were living and well, and 1 was living with evidence of recurrence. 3 patients were living after resection for benign lesions. The longest survival was 41 months. None of these showed any evidence of lymph node metastases at the time of operation. Five of 37 patients survived or are living 3 years after operation, an average of 13.6 per cent.

The 17 patients who survived operation but died later survived for an average of 18 months. Fourteen died of their original cancer. The average duration of life in this group was doubled if no lymph node metastases were found at the time of the original operation.

ROBERT R. BROWNE, M.D.

The Role of Hostility in the Pathogenesis of Peptic Ulcer. THOMAS S. SAADE, ERWIN LUTIK, JOSEPH B. KREMER, and WALTER LINCOLN PALMER. *Psychosomatic M* 947 9-33

The interrelationship between psychologic and physiologic processes in the functioning of the human stomach has been known since Beaumont's work in 1833. Alexander's recent work has provided considerable psychologic insight into the role of emotional factors in peptic ulcer.

Although the increased secretion of acid gastric juice in the presence of anger has long been known, little is known of its importance in the pathogenesis of peptic ulcer.

The authors present a case of peptic ulcer in which it was demonstrated that anger stimulated the production of a large volume of gastric juice with a high free acid. This effect was produced after a period of complete inhibition of gastric acidity by enterogastrene. After bilateral vagus section the stimulating effect of anger was abolished.

In order to account for the role of anger and fear in gastric function a theoretical formulation emphasizing the specific type of correlation between these affective states and feeding is presented. This differs from Alexander's concept that the stimulus is represented by a conflict situation. There is a close emotional association in the infant between anger (crying) and the natural result (receiving food) on the one hand, and between fear and the feared result (not receiving food) on the other. In the course of normal development this equation is weakened or broken. In some ulcer patients and in some normal individuals this association may persist and may then find its expression through the process of "repressive innervation" (the recapitulation of an infantile pattern of physiologic responses to certain emotional stimuli mediated by nervous pathways).

The etiology of peptic ulcer is complicated and probably includes a multiplicity of somatic and psychologic factors. In considering psychologic factors we must assume that anything which increases the gastric secretory and motor activities may cause an ulcer. On this hypothesis, hostility is a potential

pathogenic agent for peptic ulcer. Regardless of the difficulty in estimating its importance quantitatively it must be considered to play a major role.

ROBERT R. BIGGLOW M D

The Place of Surgery in the Treatment of Peptic Ulcer. The Hamilton Russell Memorial Lecture. SIR HERMANCE O'CALLAGHAN, *Austral N Zealand J Surg* 1947 17 3

The author presents a long philosophical discussion of the physiology of the stomach, particularly as related to peptic ulcer, the symptomatology of peptic ulcer, and the author's evaluation of current trends in the operative treatment.

It is emphasized that gastric and duodenal ulcer are separate disease entities despite some similarities. Gastric ulcer is an old disease (becoming less common) that occurs in the undernourished and underprivileged all over the world. It occurs equally in the sexes usually in the long low stomach of poor tone, slow emptying and a low or normal acidity. Oral sepsis and food of poor quality or insufficient amount often seems in part responsible. Gastric ulcers undergo malignant degeneration in about 5 per cent of cases but apart from this are seldom fatal, however, once they become chronic they rob life of all its pleasures. Causes of persistence probably lie in the stomach itself, the avascular scar, and the adhesions.

Duodenal ulcer is a new disease. It is limited to civilized communities and the more progressive members of those communities and is becoming commoner. It occurs more frequently in men, brain workers of the restless intellectual worrying type, but its occurrence in women is increasing as they take over the activities of men. It occurs more often in the high transverse type of stomach and the onset and recurrences are frequently associated with periods of worry, overwork, and frustration. Surgery for duodenal ulcer is the surgery of the complications as contrasted with gastric ulcer in which operation is performed because of persistence.

The desirable treatment of gastric ulcer is gastrectomy which at one step removes the symptoms, the ulcer, and the dominant factor causing the ulceration. Vasoligation of large numbers of the arteries of the stomach just short of gangrene as a method of reducing the acidity is dismissed because gangrene and slough has been a complication and otherwise the operation is frequently a failure because of inadequate ligation.

Vagus section is thought to be of value but is considered inadequate because it only affects the psychic phase of gastric acid secretion leaving the prolonged effect of the hormonal stimulation from the retained pyloric end of the stomach.

The exclusion operation in which the pylorus with the ulcer is allowed to remain distal to the resected area of the stomach is also condemned because it leaves the hormonal secreting portion of the stomach. When this procedure is necessary because of technical difficulty in removing the ulcer area the

mucous membrane as far as the pyloric ring should be removed.

The three roots from which gastric acidity springs must be removed for adequate treatment of duodenal ulcer. First, the zone of high gastric secretion should be completely removed, that is the area of high convoluted mucous membrane of the body should be removed leaving only the low acid secreting mucous membrane of the fundus. Second, a high proportion of the vagal fibers should be removed. Third, all of the pylorus or at any rate all of the pyloric mucous membrane should be removed.

The author prefers for duodenal ulcer a gastrectomy at the level of the lower end of the fundus with a retrocolic valvular type of anastomosis with the jejunum. He straightens out the duodenojejunal junction by freeing the ligament of Treitz. The anastomosis is isoperistaltic, is entirely superior to the mesocolon and falls in a smooth curve to avoid obstruction and resultant duodenal blow-out.

FREDERICK C. HORBEL, M D

Symposium on Vagotomy for Peptic Ulcer. Experimental Observations. HENRY N. HARKINS, DONALD H. HOOKER, T. CRANDALL ALFORD JR., JOHN CALLANDER and Others. *Bull Johns Hopkins Hosp* 1947 81 9

The authors performed 6 different experiments on the production and prevention of peptic ulcers.

1 They attempted to produce histamine ulcers in the rat.

2 They used aqueous benadryl solution in an attempt to prevent histamine in beeswax ulcers in the guinea pig.

3 They used benadryl in beeswax in an attempt to prevent histamine in beeswax ulcers in the guinea pig.

4 They used vagotomy in an attempt to prevent histamine in beeswax ulcers in the guinea pig.

5 They used vagotomy to prevent pyloric ligation induced ulcers in the Shay rat.

6 They studied the influence of vagotomy on the development of jejunal ulcers in the Mann-Williamson dog.

The various experiments warranted the following conclusions:

1 Benadryl (per os or subcutaneously in aqueous or in beeswax in-oil solution) does not prevent histamine-provoked peptic ulcers in guinea pigs within the limits of dosage and conditions of the experiments reported.

2 Vagotomy does not prevent histamine provoked ulcers in guinea pigs within the limits of dosage of the drug as used.

3 Vagotomy prevents the development within 24 hours of ligation induced ulcers in rats and lengthens the life of such animals.

4 Vagotomy lessens the acidity and volume of the accumulated gastric fluid following pyloric ligation in rats, but neither of these factors alone explains the beneficial effect of this procedure.

5 Esophageal ligation with or without vagotomy reduces the incidence of pyloric ligation induced ulcers in rats, but does not prevent them entirely.

6 Vagot my performed an average of 51 days after Alann Williamson operations in dogs reduced the incidence of peptic ulceration following this operation from a control level of 85 per cent to 11 per cent.

JOSEPH CARTER, M.D.

Symposium on Vagotomy for Peptic Ulcer Early Surgical Results in 43 Cases. THOMAS V. P. JORDAN and WILLIAM E. GROCK. *Bull Johns H ph ns II* p 947 8 9

Vagotomy for peptic ulcer has been performed on 43 patients at the Johns Hopkins Hospital Baltimore Maryland. In this series 4 different operative procedures have been used.

1 Tran thoracic vagot my with division of the greater splanchnic nerve on one side was performed on 3 patients.

2 Vagotomy alone was done in 16 cases (trans-thoracic 11 abdominal 5).

3 Vagot my with gastroenterostomy was done in 8 cases and with Finney pyloroplasty in 2 cases.

4 Vagotomy and gastric resection was done in 14 cases (Polya 7 Hofmeister 7).

The clinical results in 34 (83%) of the 41 patients followed from 10 to 24 months have been satisfactory in the remaining 7 cases (17%) they were unsatisfactory. Excluding the 1 patient who died with complication of craniotomy and 3 patients in whom vagotomy was complicated by simultaneous division of one splanchnic nerve, the corrected results are no mortality in 37 patients satisfactory results in 33 or 89 per cent and unsatisfactory results in 4 or 11 per cent. The 2 patients not followed up were doing well at the time of discharge.

In the satisfactory results, the cessation of ulcer pain has been most striking and has overshadowed other troublesome, although transient, effects of vagotomy. These, in order of frequency have been (1) an increase in the number of daily stool with occasional diarrhea, (2) postprandial fullness, and (3) occasional postoperative vomiting, the latter two effects being related to the motor paralysis of the stomach which followed vagotomy in 24 patients.

Of the patients with unsatisfactory results 3 have come to reoperation 1 for recurrence of ulceration and 1 for intractable gastric retention and dilatation due to vagot my motor paralysis. There are 3 patients in this group who have continued to show uncontrollable signs of severe gastroparesis and may need gastroenterostomy in the future.

All of the failures occurred in the patients who had vagotomy without any additional operative procedure either plastic or ablative on the stomach itself. The results have been uniformly satisfactory in the 24 patients undergoing some such procedure in addition to vagotomy. The most satisfactory results 11 occurred in the 10 patients in group 3 who had gastroenterostomy or pyloroplasty along with the vagotomy.

JOSEPH CARTER, M.D.

Symposium on Vagotomy for Peptic Ulcer Medical Aspects of Vagotomy for Peptic Ulcer including Observations on the Clinical Value of the Insulin Test and on Postoperative Criteria for the Completeness of Bilateral Gastric Vagus Section. MORRIS PAULSON and EUGENE S. GARDNER. *B H Joh H ph ns II* p 947 8 107.

The authors analyze the same 4 groups of patients as in their previous article omitting the group in which vagotomy with splanchnicectomy was done.

The most striking result was complete cessation of pain. The complete relief of pain after vagotomy is not an unmitigated blessing. Recurrent ulceration, perforation, and obstruction may be difficult to recognize. All the patients undergoing vagotomy alone complained of varying degrees of failure. Diarrhea was brief and readily controlled.

X rays showed gastric dilatation and atonic and peristaltic diminution. By the end of the first postoperative year most of the stomachs showed normal tonicity.

Gastroscopy showed a patulous antrum and lessened peristaltic activity after vagotomy. After subtotal gastrectomy and vagotomy gastroscopy frequently showed edema erosion hypertrophy and friability in the residual gastric pouch and the attached jejunum.

JOSEPH CARTER, M.D.

Surgical Ascariasis (Ascariidosis chirurgica). D. FEN and O. JELKOWSKI. *Arch Ital mal pp diger* 941: 13 390.

The author reports 5 cases of ascariasis, as follows:

1 Perforation of the small bowel. A female worm and purulent fluid were found at operation. The perforation about 5 mm. in diameter, was closed and the abdominal wound drained. The patient died after a period of 36 hours. A partial autopsy was performed and the perforation was found to be adequately closed. Diffuse purulent peritonitis was present, and 14 other worms were found in the intestinal lumen. The literature is reviewed and ample confirmation is cited to show that ascariasis infection can be followed by perforation due to traumatic activity caused by the parasite.

2 Postoperative duodenal fistula following a gastric resection (Polya Reichel). The patient discharged dead female worm on the eighth day, when the wound was incised because of infection. On the twelfth postoperative day 3 living worms were found beneath the dressing. The condition rapidly became worse and antihelminthic therapy was started, with prompt response and improvement. The patient vomited 20 worms, 7 were expelled through the duodenal fistula, and 13 in the stools.

3 Chronic appendicitis with female ascariasis in the lumen of an appendix about 8 cm. in length and of the calibre of a pencil.

4 and 5. Intestinal obstruction. Operation performed in both cases and the small bowel was opened for removal of the parasites. The first patient age 6 was taken home after the second day in

a critical condition and no further notation was made. The second patient age 11 was operated upon in 1941 with an uneventful recovery. She was again operated on in 1943 for the same condition which was complicated by wound infection and fecal fistula and the patient died after 1 month's hospitalization.

An interesting review of the literature with special emphasis on pathogenesis is presented. Perforation of the bowel is ascribed to traumatic activity while obstruction is caused by grouping of the worms thus forming a mechanical block. Small doses of anthelmintics may be a factor in merely stimulating the worms to move and thereby causing a mass large enough to obstruct.

LUCIAN J. FROEDT, M.D.

Benign Intestinal Tumors of Vascular Origin
JOSEPH A. LAZARUS and MORRIS S. MARKS. *Sur gery* 1947 22 766

A total of 38 cases has been reported including 9 of the authors. The age incidence of the patients varied from 2 months to 81 years. Twenty three of the tumors occurred in men and 15 in women. Bleeding was the most constant symptom (in 69.2%) and intestinal obstruction was noted 5 times. Fourteen of the lesions were located in the small intestine, the others were scattered throughout the bowels. Fifteen of the tumors were found only at necropsy and were without clinical symptoms.

The lesions found were nevi (6), angiomas (11), cavernous angiomas (11) and capillary hemangiomas (5).

The tumors may occur singly or multiply.

FRANK B. QUINN, M.D.

Solitary Neurofibroma of the Small Intestine. WERNER MÖLLER. *Acta chir scand* 1947 96 1

The author describes the case history of a 40 year old man with a neurofibroma the size of a human head which was removed from the small intestine. The localization, anatomic peculiarities and symptomatology of intestinal neurofibromas are discussed. From a surgical standpoint these lesions probably should be considered potentially malignant and should be treated by intestinal resection rather than by simple removal.

EDWARD W. CRESS, M.D.

Talcum Powder Granuloma: A Frequent and Serious Postoperative Complication. BEN EISENMAN, M. G. SKELLO and NATHAN WOMACK. *Ann Surg* 1947 126 820

The authors present 37 cases of postoperative complications due to talcum powder granuloma. These cases represent a wide diversity of complications ranging from simple wound abscesses to serious sequelae such as fecal fistulas and intestinal obstruction. The clinical and pathologic nature of this condition is discussed. Emphasis has been placed upon the requirements of a suitable alternative dusting powder for use in the operating room. The best answer to the problem is believed to be the

use of wet gloves or the substitution of an innocuous dusting powder. Potassium bitartrate, properly sterilized, can be used. Talcum powder must be banned from the field of surgery.

The authors review their experimental and clinical work with formalized starch compounds. The starch compounds as now produced are not completely stable, and must be further modified before their use can be recommended.

CHARLES BARON, M.D.

Megaduodenum: A Clinical Study (Sul megaduodeno studio clinico) ATTILIO BASILE. *Ann ital chir* 1947 24 233

The case report of a 42 year old patient with megaduodenum is presented. Symptoms began at 12 years of age. About 10 years ago a gastrojejunostomy was performed. This was followed by relief for a period of 1 year after which the symptoms returned; these became worse following a second operation which consisted only of a viscerolysis and the patient had to resort to the frequent use of opiates. The symptoms consisted of pain after meals vomiting after meals and with a fasting stomach, anasthesia and loss of weight.

X ray studies revealed a functioning gastroenterostomy, high lying, which did not empty the entire stomach. The opaque meal which passed through the stoma was readily carried on through, but that which passed through the pylorus showed a marked distention of the horizontal portion of the duodenum.

The patient was subjected to a third operation in which the adhesions were separated, the gastrojejunostomy was taken down, the jejunum was resected in the region of the stoma with end-to-end anastomosis and a Polya type gastric resection and duodenojejunostomy by the method of Braun were carried out. The patient made a good recovery with no recurrence of symptoms even after returning to strenuous work.

In discussing the symptoms, the author states that the clinical diagnosis is difficult. The two differentiating points are (1) onset of gastric disturbance in early childhood and (2) retention vomiting with bile in contradistinction to retention vomiting of pyloric stenosis which does not contain bile. The x ray studies usually lead to the diagnosis.

As to therapy Basile states that some authors recommend medical management. However he believes that the treatment is exclusively surgical and that medical management usually results in a far advanced condition and a poor risk patient. It is much better to operate before this state ensues.

LUCIAN J. FROEDT, M.D.

Subcutaneous Retroperitoneal Duodenal Rupture. GUNNAR K. LAURITZEN. *Acta chir scand* 1947 96 97

Subcutaneous retroperitoneal duodenal rupture is a rare lesion with a bad prognosis. However the author reports a personal case with favorable outcome treated by bowel suture and drainage as well as extraperitonealization by suture of the anterior

to the posterior peritoneum. This method was employed even previously also with recovery. The present case is the third recovery reported in Sweden.

Because of the rare occurrence of this trauma there is no course which may be considered typical, practically every case having its distinct problems. The etiology is occupationally determined but tends in our day to be due to motoring. Recently due to the war explosions in the water have been reported to result in well defined ruptures which are easily amenable to suture. Subcutaneous retroperitoneal duodenal rupture is localized to the second and third portion of the duodenum in 50 per cent of the cases.

The diagnosis is difficult because of the absence of the symptoms of peritonitis usually so alarming in intestinal rupture. X-ray examination rarely gives information by revealing a retroperitoneal emphysema. Without operation the course is nearly always fatal. The indications for explorative laparotomy are augmented by the fact that early operation decides the prognosis. It is generally easy to detect the presence of a serious internal lesion.

At operation a retroperitoneal edema usually translucent and suggesting underlying blood or bile, and a palpable or visible emphysema suggest duodenal trauma. The recognition of this is important, as in approximately every fourth case the picture has been interpreted as a contusion and the lesion has not been detected. Coincident lesions must not distract due attention. A most careful exploration of the entire duodenum must be done as several ruptures may occur simultaneously or a nonperforating lesion of the wall or a loosening of the bowel may be present and present the risk of a secondary perforation.

It appears that simple suture has been done most frequently. Each case however must be treated individually also in regard to palliative or prophylactic measures. The least intervention possible should be the aim. Drainage is advisable also in conditions favorable to suture.

The prognosis is precarious. The total material shows recovery in about 32 per cent of the cases. For the last 35 years recovery has taken place in about 50 per cent of the cases. However these figures may be unduly favorable as cases with a lethal course may not have come to publication.

H. J. & GOLDMAN, MD

Acute Diverticulitis of the Cecum. L. ANDERSSON
Surgery 947 479

Although diverticula of the cecum are considered rather rare the author was able to find records of 99 cases in which operation had been performed because of acute diverticulitis of the cecum. The average age incidence of the patients was less than 40 years, which is much lower than that for diverticulitis in the remainder of the colon. The cases were about equally distributed between the two sexes which is also different from the findings in most studies on surgical diverticulitis, which show a preponderance of males. More than a third of the surgeons performed extensive operations such as resection of the

cecum or right colectomy. This is understandable in view of the difficulty of distinguishing a perforated and inflamed diverticulum from carcinoma at operation. Eighty-four per cent of the surgeons listing a preoperative diagnosis thought the appendix to be the cause of the patient's symptoms previous to operation.

We believe that acute diverticulitis of the cecum is a surgical disease and will continue to be so for a long time to come, since it seems very difficult to distinguish from appendicitis preoperatively and since roentgenologic studies of the colon following barium enemas are usually contraindicated when the most probable diagnosis in a case is appendicitis.

A Consideration of Pathological Factors Influencing 5 Year Survival in Radical Resection of the Large Bowel and Rectum for Carcinoma. R. K. GILBERT and VERNON C. DAVID. (Am Surg 1947) 26 4

The authors' study is an extension of their previous work. It is based on the clearing of specimens, and the meticulous dissection of lymph glands which are charted as to their anatomical location and studied microscopically to determine the presence of tumor cells. The thoroughness of their work is indicated by the large number of glands found in each patient (an average number of 55 per patient) as compared to the number of glands found in a routine pathological examination.

Two hundred cases were studied. The operability rate was 75 per cent and palliative resections are not included in the statistics.

The tumors were grouped anatomically into four divisions. One group included patients with lesions of the right half of the colon and the first 3 inches of the transverse colon. A second group included tumors of the left half of the colon, the remaining transverse colon and the descending colon to the redundant loop of the sigmoid. The third group comprised tumors of the redundant sigmoid down to and including the pelvic peritoneal floor which lesions were entirely covered anteriorly by peritoneum. The fourth group was made up of all other lesions grouped together as extraperitoneal rectal tumors.

Fifteen patients had tumors of the right half of the colon, 13 had nodal involvement and of these, 7 (53.8%) were alive 5 years or more following resection. The 2 patients without nodal involvement were alive 5 years after resection.

Of 18 patients with tumors of the left half of the colon, 8 had nodal involvement and of these 3 (37.5%) were alive after a period of 5 years of the 10 patients without nodal involvement, 8 (80%) were alive after 5 years. Although only 44 per cent of the tumors in this region had nodal involvement—a lower percentage than that in the other regions—death from recurrence was relatively higher which would suggest that resections in this area generally are not wide enough.

Of 55 patients with tumors in the redundant sigmoid 35 had involvement of the nodes and 9 (51.4%)

of these were alive after a period of 5 years 20 patients were found to have no nodal involvement and 18 of these (90%) were alive after a period of 5 years.

There were 112 patients with carcinoma of the extraperitoneal rectum 69 of whom had nodal involvement and of these 26 (37.5%) were alive after 5 years. Of the 43 without nodal involvement 32 (74.4%) were alive after 5 years. Local recurrence was great in this group.

Fifty seven per cent of all of the patients in this series were alive 5 years or more after resection 78.5 per cent of the total number of patients without nodal involvement were living from 5 to 10 years after surgery.

Three women were pregnant when the diagnosis of tumor was established and 2 of these were living after a period of 5 years.

Forty per cent of the patients requiring resection of adjacent structures because of their adherence to the cancerous portion of the colon survived for a period of 5 years or more. This figure could be improved by chemotherapy and supports the trend to radical resection in such cases.

The dissections revealed several other important findings. Retrograde metastases 1 to 5 cm below the tumor occurred in 7 of the 153 tumors below the promontory of the sacrum. In 8 of the patients who died following surgery all of the retroperitoneal tissues from the celiac axis to the base of the bladder were cleared and studied. Two patients who were without nodal involvement at surgery were found to be free of involved nodes in the postmortem specimen 4 patients who had nodal involvement at surgery had further involvement in the cleared specimen and of these 3 would have been cleared of involved nodes if the operative dissection had been 1.5 cm wider.

FREDERICK C HORNER, M.D.

A Suspension Operation for Prolapse of the Rectum THOMAS G ORR, *Ann Surg* 1947 126 833

A suspension operation for complete prolapse of the rectum is described. Two strips of fascia from 1 to 2 cm wide and from 10 to 12 cm long are excised from the fascia lata. A left paramedian incision is made from the pubis to a point about 2 cm above the umbilicus. The patient is placed in the Trendelenburg position and the abdominal contents are packed away from the pelvis with warm moist pads. A tape is passed through the mesentery beneath the lower

Fig. 1 (Orr) A, B, C Technique of removal of fascial strips from fascia lata.

Fig. 2 (Orr) Fascial strips sutured to rectal wall and to fascia above the promontory of the sacrum. On the left the fascial strip is passed through the mesentery of the sigmoid.

Fig. 3. A fold of peritoneum has been sutured to the rectal wall on each side to cover the fascial strips. The cul-de-sac has been obliterated by rows of sutures placed transversely across the pelvis.

Fig. 4 (Orr) A Detail of attachment of fascial strips to fascia above the promontory of the sacrum. B Lateral view of pelvis showing closure of cul-de-sac and location of fascial strip on wall of rectum. (Courtesy of J. B. Lippincott Co.)

sigmoid for traction. Gentle traction will hold the prolapsed rectosigmoid in normal position. The fascia just above the promontory of the sacrum is exposed through an inverted T-shaped incision in the peritoneum. A strip of fascia is sutured to each side of the rectum with a double row of interrupted sutures of fine silk. The strip of fascia on the left is passed through a puncture wound made in the mesentery of the sigmoid. While the rectum is held suspended, the upper ends of the fascial strips are sutured to the dense fascia above the promontory of the sacrum. Interrupted silk sutures are used to attach both margins of the fascial strips to the fascia, a distance of at least 1 cm. The cul-de-sac is completely obliterated by two or more rows of interrupted silk sutures placed across the pelvis. The peritoneum is sutured to the anterior wall of the rectum as each row of sutures is placed. The pelvic operation is completed by suturing a fold of peritoneum to the rectum on each side to cover the fascial strips. The abdominal and thigh wounds are closed with silk.

The results in the 4 cases have been satisfactory. There has been no evidence of recurrence of the prolapse, and the function of the rectum has been normal. The possibility of constriction or angulation of the lower sigmoid at the sacral promontory was considered but this has not happened. A barium enema showed a normal caliber of the rectosigmoid in 3 cases.

CHARLES R. ROY, M.D.

Considerations of Proliferative and Stenosing Proctitis (Considérations sur les rectites proliférantes et sténosantes) MARIN PORCECO-URIBE and C. AZCUTTE. *J. chir. P.* 1947 63: 365.

This disease which appears to be a definite clinical entity remains a complex problem. There are factors which suggest a lymphogranulomatous origin but the virus found at the border of the rectal lesions cannot be cultivated and reinoculated

to produce the disease. Other factors suggest that the lesion may not be of lymphogranulomatous origin.

The authors have reviewed 31 cases and believe that there is a direct connection between the virus of Nicolas and Favre and Ducrey's bacillus in the production of proliferative and stenosing proctitis. The organisms may be inoculated by the rectal or vaginal route but the lesions always begin at the border of the rectal mucosa and spread distally and proximally. The associated periproctitis is not a cause but a result of the rectal lesions.

EDWARD W. GIBBS, M.D.

Surgical Treatment of Proliferative and Stenosing Proctitis. Operative Technique (Le traitement chirurgical dans les rectites proliférantes et sténosantes. Technique opératoire) MARIN PORCECO-URIBE and C. AZCUTTE. *J. chir. Par.* 1947 63: 379.

The authors recommend surgical treatment as the treatment of choice for proliferative and stenosing proctitis. The most ideal operation would seem to be a rectocolic resection by the abdomino-endo-anal route with re-establishment of bowel continuity.

This procedure allows one to get beyond the limits of the disease, preserves as much intestinal motility as possible for subsequent anastomosis, permits a smaller amount of endo-anal dissection, and avoids operation through areas of fistulous tracts and elephantiasis.

The preoperative care, selection of anesthesia, operative technique, and postoperative care are discussed. Accidents and postoperative complications are enumerated.

EDWARD W. GIBBS, M.D.

Carcinoma of the Rectum JOHN TURNER. *Austral. N. Zealand J. Surg.* 1947 17: 5.

An analysis of the records of carcinoma of the rectum in three teaching hospitals in Melbourne is presented—190 cases in 10 years.

Means whereby the operability rate could be increased and the mortality rate decreased are suggested.

1. The adoption of the combined type of operation (abdominoperineal or perineoabdominal) as a standard method of approach. It is considered that this method allows more patients to be included in the operable group.

2. A more liberal view of the assessment of operability. As in any form of malignant disease, the operability depends upon (a) the presence or absence of metastases (b) the fixity of the tumor and (c) the general condition of the patient.

a. The presence of metastases (after clinical examination or abdominal exploration). Cases falling into this category need no comment and do not affect this discussion.

b. Fixation of the growth. Local records show that fixation of the growth is the most common contraindication to resection. A bolder approach to this problem seems warranted. It is frequently found that a growth apparently fixed in one or another

direction is readily removable. This is particularly the case when the growth is fixed posteriorly or when it is adherent to the vaginal wall. The estimation of what can be adequately removed is obviously a matter of considerable experience and judgment. Rectal examination is the deciding factor in growths situated in the lower and middle thirds and in a few cases with intussusception in the upper third. Placing the patient in the right lateral position and examination with the left index finger, as suggested by Miles, are of the greatest assistance in a difficult case. When the growth cannot be examined completely in this manner the decision as to mobility must be delayed until laparotomy is performed.

c. The general condition of the patient. The majority of younger people suffering from the disease are in satisfactory condition or can readily be brought into a satisfactory condition by suitable preoperative treatment. The most common consideration is old age and its associated cardiovascular and renal disease and these are frequently cited in case histories as a contraindication to removal, particularly when resection appears difficult on clinical examination. However with well planned preoperative and postoperative management it is surprising how well such patients stand radical operative procedures. Old age, arteriosclerosis and renal insufficiency should be treated on their merits and if they are not likely to cause the early demise of the patient *per se*, resection should be performed if the condition is otherwise operable.

The use of colostomy in cases regarded as inoperable is discussed.

Combined perineoabdominal excision without preliminary colostomy is recommended as the method of choice in the majority of cases.

The importance of the preoperative and postoperative treatment is stressed and described as used.

The postoperative complications are discussed, with particular reference to bladder dysfunction and to complications arising from the colostomy.

The care of the colostomy is described in detail.
JOHN J. MALONEY, M.D.

Anorectal Malignant Melanomas. OTTE MULLER.
Acta chir. scand., 1947 90: 39.

Malignant melanomas seldom occur in the gastrointestinal tract, but when they are found there they are mostly in the region of the anus. About 80 cases of melanoma situated in the rectum have been reported in the literature. These constitute from 2 to 3 per cent of all malignant melanomas.

The mean age of the patients is about 50 years and the ratio of men to women is 18 to 10. While the melanoma varies widely both as to quantity and mode of appearance there is more pigmentation in the tumors situated nearest the anus. Melanoblasts are derived from the ectoderm which is the probable origin of melanomas.

The clinical picture is partially characteristic since melanomas are solid with no tendency toward circular growth but with considerable infiltration

in the rectal wall. Ulcerations are superficial there is no necrosis or crater formation. The infiltrative characteristics make radical surgery necessary with removal of the regional lymph nodes—in this case the retrorectal nodes. The necessity for careful dissection of lymph nodes even if they show no clinical signs of tumor is stressed.

Malignant melanomas possess a pronounced tendency to metastasize. Approximately 87 per cent metastasize to the liver and 50 per cent to the lungs and pleura. The retrorectal nodes are involved much more frequently than the inguinal nodes.

Radiosensitivity is generally slight although exceptions have been reported.

The mortality is about 78 per cent with a 5 year cure rate of not more than 13 per cent.

FRANK B. QUINN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

On the Surgical Aspect of Acute Hepatitis. ERNST BERGMAN.
Acta chir. scand., 1947 96: 17.

The author contends that acute hepatitis, while primarily a medical disease often becomes complicated by accumulations of mucus which produce obstruction in the lower part of the common bile duct. This obstruction is sufficient to stop the flow of bile which is under subnormal pressure as a result of the hepatitis.

Surgical intervention was carried out in 7 cases of this type in which the jaundice was not relieved by medical therapy. The biliary passages were perfused with cholangiographic contrast matter and in some instances, normal saline solution was added. Following the operation the jaundice disappeared rapidly and the patients recovered.

EDWARD W. GIBBS, M.D.

Hepatic Calculi. ANTHONY BARKER and A. GERRARD.
Peters. Am. J. Med. Sc. 1947 314: 433.

Hepatic calculi have been found in as high as 7.6 per cent of some series of cases of cholelithiasis. The immediate mechanism causing the formation of the stones is probably chemical. They present no characteristic symptomatology and the symptoms if present, are usually due to the coexisting cholelithiasis. The clinical diagnosis is made only by means of roentgenography and the other causes of calcification must be ruled out (hemangiomas, amebic abscess, echinococcus cyst, gummas, tuberculomas, carcinomas). If the hepatic calculi are causing no symptoms conservative treatment is indicated. Operative treatment depends in great degree on the associated findings, such as gallstones or common duct stones. In the presence of liver stones the mortality rate in operations on the biliary tract is greatly increased.

True uncomplicated hepatic calculi appear to be compatible with long life and comparative good health and thus the treatment should be conservative. In the presence of complications, such as

liver abscess, cholelithiasis, cholangitis, and common duct obstruction the treatment should be directed to eradicate the complication.

F. J. LAMARCA, JR., M.D.

The Innervation at the Junction of the Common Bile Duct and the Duodenum from a Surgical Point of View CURT FRANKSON *Acta chir scand.* 947 96 63.

The author made a detailed study of the innervation at the junction of the common bile duct and the duodenum with the object of providing an anatomical basis for surgical operations in this region.

The study was made on postmortem cases that did not show morbid changes within the area examined. The course of the nerves was studied macroscopically and microscopically.

The celiac plexus is regarded as a unit having several communications with the sympathetic trunk.

The duodenal papilla (Vater) is innervated mainly by the common bile duct nerves, which run from the dorsal hepatic plexus along the common duct. Fine nerve communications, pancreatic nerves, have however been found along the pancreatic duct.

The nerves to the upper part of the duodenum and pylorus are described.

The possibilities of denervating the duodenal papilla (Vater) are discussed and a suitable technique for the purpose is described.

The nerve plexus on the anterior aspect of the aorta, the bulk of which is situated just below the diaphragm, provides a large part of the abdominal viscera with autonomous innervation. It is termed the celiac plexus and is sometimes described as being divided into two branches, one on the right and one on the left side of the aorta. This division, however, is anatomically vague and is scarcely justifiable from a surgical point of view.

The celiac plexus is provided with sympathetic nerve fibers which pass mainly through the three splanchnic nerves. By the close relation to the abdominal aortic plexus, however, ample provision is made also for other communications with the sympathetic trunk.

Parasympathetic nerve fibers are distributed to the celiac plexus from the posterior vagus trunk, according to McCrea, through a large nerve trunk issuing just below the diaphragm and following the posterior abdominal wall. The anterior vagus trunk, according to McCrea, is in communication with the celiac plexus by nerve fibers running across the uppermost part of the stomach and then following the left gastric artery.

From the part of the celiac plexus lying between the aorta and inferior vena cava a group of nerve fibers proceeds toward the right. These fibers are usually divided into three main trunks. This group is termed by several authors (Latarjet and Alexander) as the plexus hepaticus posterior (dorsalis). These nerves pass dorsal to the portal vein. They reach the caudal part of the epiploic foramen (Winslow) and run there in a ventral direction.

The largest branches join the cystic and hepatic ducts reaching the gall bladder and liver, respectively. Two or three finer branches about a millimeter in thickness, branch off in a duodenal direction and join the common bile duct. They also send some fibers to the pancreas which, in addition, receive nerves from the celiac plexus along its vessels.

The nerves that join the common bile duct approach the latter from the dorsal side, giving off small branches to the duct which gradually merge completely with its wall. Sometimes one finds a nerve branch running through the pancreatic head and reaching the common bile duct near the duodenum. Macroscopically the nerves can be followed to about 1.5 cm. from the place where the common bile duct pierces the duodenal wall, and by means of a microscope, they can be followed 1 or 2 cm. further. They are finally merged completely in the common bile duct wall. The nerve fibers have been followed further toward the tip of the duodenal papilla with the aid of a microscope and serial sections. In the sections the nerves become finer as they approach the tip of the papilla. Here and there ganglion cells adjoin them. The entire papillary area has been sectioned and nerves, although very fine, were found right out to its extremity. They are distributed in all layers of the wall.

Under the microscope it can also be observed that a few fine nerves, after passing along the pancreatic duct, reach the papillary area. Through these nerve fibers and the pancreatic nerves, there is a closer communication between the papillary area and the celiac plexus.

No direct communications with the nervous apparatus of the duodenal wall have been observed, although with the histological methods adopted here, very fine communications of this nature cannot be completely ruled out. The well delimited nervous apparatus which was detected indicates, however, that such communications with the duodenum are scarcely of any great importance.

A division into different nerve plexuses within the common bile duct wall (adventitial, intramuscular, submucous) as reported by Alexander has not been observed.

From the celiac plexus and around the celiac and hepatic arteries there is another nerve plexus, (plexus hepaticus anterior ventralis) according to Alexander and others, which sends three or four nerve branches toward the dorsal side of the duodenum at the triangle formed by the right gastric artery, the common bile duct, and the duodenum. These nerves anastomose with the direct vagus branch to the porta hepatis. The duodenum is also supplied with nerves from the celiac plexus which run along the blood vessels, the pancreaticoduodenal artery and the right gastroepiploic artery.

About 1 cm. below the diaphragm, the left vagus nerve (the anterior vagus trunk, according to McCrea) gives off a branch which passes toward the porta hepatis through the lesser omentum. A minor part of this branch bends off toward the pyloric area,

where it branches out to supply the uppermost part of the duodenum, the pylorus and the adjacent part of the prepyloric area. The nerve fibers to this region can be followed for about 3 cm. toward the cardia where they meet the nerves coming from the upper end of the stomach. No actual communication between them has been observed but they overlap in distribution.

Near the junction of the cystic and hepatic ducts there are some fine anastomoses between the nerves of the common bile duct and the nerve fibers winding around the hepatic artery. (They correspond to Alexander's anastomoses between the anterior and posterior hepatic plexus.)

To regard the celiac plexus as being divided into a right and a left part is scarcely warranted from a surgical point of view. It would be more correct to regard the celiac plexus as a unit.

Besides the splanchnic nerves, the celiac plexus has several communications with the sympathetic trunk through the abdominal aortic plexus.

"*Nervi choledochi et pancreatici*" is the term used by Swan Latarget *et al.* Raigorodsky, Alexander Reich and Perman to describe a nerve which runs along the dorsal side of the common bile duct. The description ends with the nerve at the duodenal wall.

No statements have been found regarding nerve communications along the pancreatic duct.

The present investigation has shown that there are several nerve trunks passing along the common bile duct in the duodenal direction (*nervi choledochi*) and that more than one of them reach the nerve mechanism of the duodenal papilla. A nerve communication from the papillary region along the pancreatic duct (*nervi pancreatici*) and the pancreas to the celiac plexus has, moreover, been observed.

Alexander's division of the nerves of the common bile duct wall into different plexuses (submucous, intramuscular, adventitial) has not been verified. For this purpose however a different histological technique is presumably required.

The results of this investigation of the duodenal nerves correspond in essentials with the findings of Swan Latarget *et al.* Raigorodsky and Perman, i.e. nerve trunks arise from the celiac plexus and pass from there along the common bile duct to the duodenum.

McCrea and Perman describe the pyloric nerve as innervating the uppermost part of the duodenum and pylorus. Similar conditions have been shown by this investigation. The finer nerve fibers were followed in the prepyloric area right up to the place where (about 3 cm. from the pylorus) they meet the nerves coming from the upper end of the stomach.

The same anastomoses as those described by Alexander at the junction of the cystic and hepatic ducts have been found.

From a surgical point of view the pyloric nerve and the nerves of the common bile duct (*nervi choledochi*) are of special interest.

The prepyloric area (*canalis ventriculi*) is known to have a powerful motor apparatus and is considered

to play an important part in the emptying of the stomach. Its acid production on the other hand is of minor importance.

The impulses through the pyloric nerve are consequently important for the emptying of the stomach whereas they are believed to have less effect on the production of acid.

A thoracic vagotomy completely cuts off the vagus supply to the stomach. In the case of an abdominal vagotomy the vagus branch to the porta hepatis and thus also the pyloric nerve can be preserved. In the latter case the acid production of the stomach may perhaps be reduced but the motility in the prepyloric area which is essential for the emptying of the stomach will be retained.

If section of the pyloric nerve is desired it is quite accessible just outside the pylorus as pointed out by Latarget and McCrea. The origin of the pyloric nerve, the direct vagus branch to the porta hepatis is in fact easily accessible in the lesser omentum a few centimeters below the diaphragm. It is almost always seen in abdominal vagus resections.

The papillary region of the common bile duct is innervated in two different ways—by the pancreatic nerves and by the common bile duct nerves.

The communication with the pancreas is extremely slender and under normal conditions seems to be of little importance. If however the other nerve communications to the papillary region are destroyed it is conceivable that the communication with the pancreas might assume greater importance. To attack it surgically seems nevertheless to be out of the question at present.

The nerves of the common bile duct are certainly the normal channel for the transmission of impulses to the papillary region. As has been described they are rather scattered at the periphery and are most closely concentrated after they have passed the portal vein at the caudal part of the epiploic foramen.

Reich (1940) and Perman (1944) have described a technique for denervation of the papillary region of the common bile duct as a remedy for spasm in the sphincter of Oddi. As the most suitable way of finding "the common bile duct nerve" they suggest that the operator enter from a ventral direction between the portal vein and the common bile duct. Here the main nerve trunks from the celiac plexus are congregated. The smaller branches of the common bile duct nerves may sometimes be quite accessible. However in cases in which there is a branch running rather far dorsally and which perhaps also passes through the pancreatic head it will scarcely be accessible by this method.

For denervation of the duodenal papilla (Vater) it is proposed that the nerves of the common bile duct be exposed and resected at the caudal part of the epiploic foramen.

The duodenum must be mobilized at the part corresponding to the common bile duct area. The common bile duct is retracted to the left and the peritoneum is divided along the caudal part of the epiploic foramen. Any subserous fat is removed. The thick

nerve trunks from the celiac plexus as well as the nerves of the common bile duct are then exposed.

The main branch of the dorsal hepatic plexus, situated nearest the duodenum, is resected as well as all of the common bile duct nerves. The resection is made as close as possible to the celiac plexus and the common bile duct.

This procedure is perhaps more difficult technically than that recommended by Reich and Perman, but, on the other hand, it yields more reliable results.

The technique of denervation of the duodenal papilla is described in the following case report.

The patient was a woman, aged 38, who 4 years previously had undergone cholecystectomy. She had been suffering for 2 years from severe gallstone-like attacks. They recurred about twice a week.

Operation (M-n) Percutaneous narkotic Pribram section. The common bile duct was easily exposed and cholangiography was attempted. Considerable resistance was encountered on the injection of the dye which ran out into the duodenum in a narrow stream. Flexible bougies Nos. 14 to 16 were passed without any noteworthy obstruction. The pressure in the common bile duct varied directly with the depth of anesthesia. Denervation of the papilla was resolved upon. Mobilization of the duodenum according to the method of Kocher, mobilization of the whole pancreatic head and division of the peritoneum at the caudal part of the epiploic foramen was done. The nerves of the papilla, common bile duct and liver were exposed. All the nerves except the uppermost of the main branch were resected. The duodenum was replaced and fixed with serous suture. Cholangiography then showed a normal passage to the duodenum. The patient has been free from pain since the operation which was done 4 months ago.

BL. JAMES GOLDEN, M.D.

A Particular Biologic Action of Blood from Patients with Acute Pancreatitis (Sopra una particolare azione biologica del sangue di pancreatiti acuti) P. AM. 208 OM and G. C. 460 OM. *Poll. I. chir. prat.* 9:47-54, 36.

The present communication has for its subject consideration of a strange case of sterile phagedena following a blood transfusion—a patient with hemorrhagic pancreatitis, and of a particular biologic reaction which can be obtained in small injected with blood of patient with acute pancreatitis.

A 40-year-old married female was treated early in January, 1945 for a blood arthropathy with intravenous choline. On the eighteenth of the month at about eleven o'clock in the morning she had received an injection intravenously. Three hours later after having eaten with a good appetite she felt a disturbance in the lower abdomen, similar to that onset of menstruation. On going to her room she was suddenly seized with violent pains in the epigastric region radiating to the right and then to the left. This was followed by meteorism and rapid pulse. Biliary colic was suspected but the pains did not respond to analgesics and the patient was sent

to the hospital. At this time hemorrhagic areas were observed on the anterior aspect of the thighs; x-ray films were negative for pneumoperitoneum, and the urine showed traces of albumin.

At operation the patient was found to have hemorrhagic pancreatitis and was given 200 cc. of whole blood and on the third day she was given 150 cc. of whole blood. On the eighteenth day she had an attack of pain similar to that experienced at the onset, and on the following day she was given a third transfusion through the right external jugular. Towards the end, the needle became dislodged and some blood infiltrated into the tissues. No transfusion reaction occurred.

The patient had repeated attacks of pain similar to those at the onset of the illness. A scab was noted at the site of the transfusion in the neck. This area became necrotic and in a period of 4 days a spreading ulcer developed which ultimately involved the supraclavicular and infraclavicular spaces.

Bacteriologic examination failed to reveal pathogenic organisms. For 35 days following the transfusion there was no rise in temperature. The patient died on March 13, 1945 following one of the usual crises accompanied by a grave hemorrhage from one of the vessels in the ulcerated area.

Because of the obscure pathogenesis of the ulcer, it occurred to the authors to inject the blood of the patient and also of the donor subcutaneously in laboratory animals. This was followed repeatedly by ulceration at the site of the injection with patient's blood. Areas injected with the donor's blood and also with that of the author did not cause ulceration. Urine injections were negative.

A second case diagnosed clinically as acute pancreatitis in a patient with duodenal ulcer was also tested in the same way. This patient was not operated upon. Diastase studies revealed 6 units per cubic centimeter in blood and 6 units per cubic centimeter in the urine (method of Wohlgemuth). This was followed by similar ulcerations at the site of injection. A year later the studies were repeated while the patient was in a quiescent stage clinically. The same ulcerations were produced with the patient's blood and negative results were obtained with the blood of normal persons.

The authors believe that if these results can be confirmed in other and more numerous cases, they can then be used as diagnostic aids.

Nitrogen and Fluid Balance in the Treatment of Acute Uremia by Peritoneal Lavage: Analysis of Peritoneal Washings for Protein, Nonprotein Nitrogen, and Phosphorus. SAMUEL H. BASKIN, HERBERT R. BROWN, JR., E. HENRY KROTH, J. JACOB HOLLER and Others. *Arch. Int. Med.* 1947, 60: 615.

Peritoneal lavage using the peritoneal surfaces in vividialysis has been performed in a number of cases.

periments during the past few years. The basis for this work is the well established fact that water crystalloids and some colloids including plasma proteins, are readily absorbed by the lining membranes of the serous cavities. It has been demonstrated further that intact erythrocytes labeled with radiodog by way of the lymphatic vessels of the diaphragm and subsequently appear in the peripheral blood.

Lavage of the peritoneum has been performed in man on a few occasions in an attempt to relieve the intoxication of uremia. Although the number of reported survivals is small (2) with a practical procedure for peritoneal irrigation such as that described by Fine and others and a more careful selection of cases, one may anticipate better results. The authors report the treatment of a patient who died but on whom it was possible to obtain considerable data on the nitrogen and fluid balances during a period of continuous peritoneal irrigation for 21 days after the onset of almost complete anuria.

A single white woman 24 years of age became ill on December 16, 1945 with nasopharyngitis caused by beta hemolytic streptococci. Four weeks later swelling of the hands was noted the blood pressure was elevated and protein was discovered in the urine. Her general condition failed to show improvement and she was hospitalized about 10 weeks after the onset of the original illness.

The electrophoretic patterns of the blood plasma and urinary proteins were determined later and were studied in detail.

An attempt was made to control edema by restricting the intake of fluid and salt but this was not successful in the general ward and the patient was transferred to the metabolic unit.

Attempts to provide an adequate caloric and protein intake were frustrated by nausea and vomiting

and it was soon apparent that the patient's general condition was deteriorating. Ammonium chloride was administered at times in the hope of producing diuresis.

She had a subacute glomerulonephritis and became almost completely anuric 2 days before the irrigation was started. Flow of urine was not re-established and the patient died.

Death occurred rather suddenly on the twenty-first day after peritoneal irrigation had been initiated. The exact reason for death is not known. It is suspected that it was due to exhaustion and shock. Autopsy was limited to exploration of the abdominal cavity.

The anatomic diagnosis was as follows: subacute glomerulonephritis, acute generalized fibrinous peritonitis, ulcerations and erosions of the gastric mucosa, fatty liver, edema and congestion of the gastrointestinal tract, edema of the retroperitoneal connective tissue and the mucosa of the urinary bladder and mild dependent edema.

The choice of peritoneal lavage as a therapeutic procedure presents several technical problems as well as ethical issues. It is obviously unjustified if there are sound reasons for the belief that renal function can never be re-established at a level compatible with survival. It adds greatly to the discomfort of the patient and to the mental anguish of the family and friends. It should not be attempted unless the onset of the anuria is acute and the chance of resolution of the lesion in the kidney within 2 or 3 weeks is good. Renal decapsulation and biopsy have been tried and might be of advantage in suitable cases. One might even question whether the procedure increases the chance of survival beyond that of more conventional methods of treatment.

The technical problems presented are those of infection, nutrition, hydration and regulation of the acid base balance.

HARRY W. FINE, M.D.

GYNECOLOGY

UTERUS

Treatment of Uterine Cancer J HEYMAN J Am
M Ass 1947 35 4 2.

According to the Radiumhemmet experience it is possible to improve the radiotherapeutic results in cancer of the corpus as well as in cancer of the cervix.

For the last 5 years about 85 cases of corpus cancer have been referred annually to the Radiumhemmet for radiotherapeutic treatment. About half of these cases are not suitable for surgical treatment either because of the spread of the growth (10 to 15 per cent of the total) or because of old age, adiposity, cardiac conditions, diabetes, and similar complicating diseases (40 to 45 per cent of the total). The

number of clinically operable cases referred to the clinic by the specialists for radiotherapeutic treatment is increasing year by year. It has thus become an important problem at the Radiumhemmet to develop a satisfactory radiotherapeutic technique for the treatment of corpus cancer.

Since 1933 a combined operative and radiotherapeutic treatment is used in which radiotherapy plays the primary and most important part. Surgery is used only in case of failure of the radiotherapy. The radiotherapeutic technique which is now used in all cases of cancer of the corpus is called the packing method. The uterus is packed with a sufficient number of uniform radium containers to completely fill the cavity. The technique was recently described in detail in the *British Journal of Radiology*. The necessary variations in the treatment times in tabular form are published in the *Acta Radiologica*.

During the period from 1914 to 1941 inclusive 842 patients suffering from cancer of the corpus were examined at the Radiumhemmet gynecologic clinic with a view toward treatment. The result estimated after a period of 5 years from the beginning of the treatment showed 44 to be alive without evidence of the disease, an absolute cure rate of 52.5 per cent.

In cancer of the corpus the result obtained with the packing method (plus operation in case of failure) is considerably superior to that obtained by surgical means alone. It seems to compare favorably with the result obtained by primary hysterectomy plus post-operative irradiation, as far as published results justify such a comparison. By primary radiotherapy equal or better results will be obtained with less risk and less inconvenience to the patients. It is obvious that the use of primary surgical intervention in cancer of the corpus will gradually be substituted by primary radiotherapy.

In the last 34 years 6200 patients with cancer of the cervix have been examined at the Radiumhemmet with a view toward treatment. All patients are traced. Precancerous conditions are included.

In 461 cases a period of at least 5 years has elapsed since the beginning of treatment. A con-

siderable improvement of the result is noticeable since 1935. The improvement is not temporary, it has been noticeable for 15 years, and consequently it is permanent. Because of the size of the samples it cannot be due to chance variations; nor can it be explained by variations in the quality of the clinical material, since 1933 there have been no such variations of any significance. Further, it cannot depend on an alteration of the routine method of brachy-radium treatment. At the Radiumhemmet the Stockholm method is still used. It has been modified only slightly since its adoption in 1914. Finally, there is no sufficient difference in the use of additional roentgen ray and telerialium irradiation to explain the improvement. There is only one acceptable interpretation: the improved results are due to superior judgment in handling the individual case, which in turn originates from increased experience.

The original Stockholm method of treatment of cancer of the cervix consists of a coincident intra-uterine and vaginal application of radium salt, screened by a filter equivalent to 3 mm. of lead. The intrauterine applicator usually holds from 50 to 60 mgm. of radium element, its length corresponding to that of the uterine canal. For vaginal application the tubes are placed in cylinders or flat applicators, which vary considerably in size. The applicators chosen in the individual treatment should be sufficiently large to cover the entire surface of the tumor and to distend the vagina laterally. As a rule they contain from 80 to 100 mgm. of radium. Gause packing provides the necessary distance between the vaginal applicators and the rectum and keeps the applicators in position.

Two treatments are given, each lasting for from 20 to 24 hours, with an interval of 3 weeks. In the 2 treatments the total intrauterine dose is between 2,400 and 2,600 mgm. hours and the total vaginal dose 4,000 mgm. hours. Supplementary roentgen radiation to the parametrium is used as a routine measure. Its value is difficult to estimate even in advanced cases. Variations in the standard technique have been adopted in recent years. The variations are mainly characterized by a 25 per cent increase of the intrauterine dose and a 10 per cent decrease of the vaginal dose. Correct use of the Stockholm method requires considerable variation in the individual case. The vaginal applicators must be chosen with regard to both shape and extent of the growth. Variations in the vaginal dose are necessary with regard to the size and shape of the applicators chosen, the width of the vagina, the age of the patient, and

number of other factors. The treatment is not varied according to the histologic character of the tumors. No practical difference has been observed in the results obtained in the treatment of various histologic types of growth. Because of the numerous variations in the type of case, in the type of treat-

Fig. 1 Different types of intracavitary radium application.

Fig. 2 Microbomb of two different designs for vaginal application.

absolute cure rate. The procedure is justifiable only if the surgical results are superior to those of radiotherapy. It is one of the most important features of radiotherapy that an early cervical cancer need no longer be regarded as a serious disease. From 65 to 80 per cent of the cases which on clinical examination are classified as stage 1 are cured for at least 5 years by radiotherapy. The risk and inconvenience to the patient are considerably less than those caused by surgical intervention. Serious injuries due to radiation are reduced to a minimum and have practically no influence on the estimation of the value of the treatment. In the hands of an expert radiotherapist serious rectal and bladder injuries are extremely rare in the early cases.

CHARLES BARON M.D.

EXTERNAL GENITALIA

Enterocoele or Posterior Vaginal Hernia. JOX VON CORY M.D., Surg. Clin. N. America 1947 37 1236

An enterocoele is a posterior vaginal hernia which consists of a small narrow thin walled sac, probably congenital in origin. It forms behind the cervix and lies between the posterior vaginal wall and the anterior wall of the rectum in the rectovaginal septum. The author states that this hernia is not a prolapse of the posterior cul-de-sac, either primary or secondary to a vaginal subtotal or total hysterectomy. If a deep posterior subtotal or total hysterectomy it should result in a prolapse of the anterior wall of the rectum through the anus. This was demonstrated by Graham in 1942.

Diagnosis is simple and accurate. The patient should be examined in the standing position with the examining finger in the rectum and the thumb in the vagina. The patient is instructed to squat or strain down. This forces air fluid or intestine into the hernia which can now be readily compressed. It will be noted that the lesion is not a rectocele but a bulge in the rectovaginal septum.

The author treats this syndrome by carefully dissecting the hernial sac from the posterior vaginal and rectal walls up to the cervix. The sac is freed and a purse-string suture is placed inside the sac and tied. The author then supplements this procedure with an abdominal operation to examine the suture line and reinforce it.

J ROBERT WILLIOW M.D.

ment, and in the patient's reaction to treatment, each of the varieties constitutes an individual problem. In recent years it has been considered advisable to modify the treatment technique in about 45 per cent of the total number of patients treated.

The identification of the cases in which a modified technique should be employed and a modified administration of the treatment require considerable experience. The technique must be varied from patient to patient and must be carefully planned from the beginning. The effect of the treatment must be closely watched during and after treatment must be time and type of subsequent treatments must be thoroughly considered. For the foregoing reasons the best results cannot be expected unless there are available a sufficient number of beds, an ample supply of suitable radium containers, and a clinic which is well organized for its special purpose. Neither can the best results be expected in places where radiotherapy is handled by a young and inexperienced assistant. In surgical therapy the results are credited to the man behind the knife. It is high time that a similar view be applied to radiotherapy.

In recent years frequent use has been made of electrocauterization in local recurrences not suitable for hysterectomy and in some types of vaginal metastases. This procedure has proved successful in controlling the cancer in a number of cases. It has proved to be a most valuable substitute for hysterectomy in cases in which it is impossible to differentiate between a radium reaction and a local recurrence. The importance of primary surgery in early cases of cervical cancer appears to be considerably overestimated. There is little reason to believe that in a series of selected cases surgical therapy would be superior to radiotherapy. In any event the slight difference between the results in such a small group of cases will never have a significant influence on the

The Occurrence of Enterococci in the Vagina of the Woman (Ueber das Vorkommen von Enterokokken in der Scheide der Frau) HARALD PEREL. *Acta obst. gyna. scand.*, 1947 27 301

The secretions from the upper third of the vagina of 276 women were inoculated in ordinary bouillon which had been enriched with phenol and bile according to the method worked out by K. Schlossmann (N. Schwarz, and K. Schlossmann. *Acta pathol. et microbiol. scand.* 1945, 22 Fasc. 3). A further method of differentiation adopted by the author was based on the resistance of the enterococcus—also known as the streptococcus faecalis—to penicillin: this organism was found to be sufficiently resistant to the drug to be of value as a means of distinguishing the enterococcus from such sensitive bacteria as the *Streptococcus viridans*. In all the strains isolated by the author the beta hemolytic type of growth on blood agar was encountered. In other authors' findings the alpha hemolytic type has predominated. In the infrequent type there is a green ring in the hemolytic area, while in the beta type the hemolytic area is violet, but it may have a slight green sheen particularly if observed at an angle. This discrepancy is believed to be due to the difference in the method of procuring and culturing the material.

The experimental material was divided into a group of 100 women in normal health (the majority of these were pregnant), a group of 108 with a variety of gynecological complaints, such as leucorrhoea, colpitis, adnexitis and Bartholinitis and, finally a group of 68 women in from the third to seventh day of the puerperium. The enterococcus was present in 16 per cent of the first group, in 17 per cent of the second group and in 33 per cent of the third group. An odd fact uncovered during the course of this study was the parallelism between the power of liquefaction of gelatine and that of coagulating milk. In the strains which liquefied gelatine the milk coagulum was of the enzyme type, with a firm contracting clabber and extrusion of the whey, when the gelatine was not liquefied a uniformly distributed coagulation, of the type produced by acids and without the squeezing out of the whey was found to result.

The author believes that the enterococcus may at times play a role in the pathogenesis of gynecologic diseases and that further research is necessary to confirm this. JOHN W. BROWN, M.D.

Primary Carcinoma of the Vagina: A Brief Review of the Literature and Reports of 4 Cases. MURIEL B. McLEATH. *Med J Australia* 1947 3

A review of the present knowledge of the pathology and treatment of primary carcinoma of the vagina is given by the author. All writers agree on the rarity of the condition and on the poor results obtained with the present methods of treatment.

The 4 cases encountered at the Royal Prince Alfred Hospital and at the King George V Memorial Hospital for Mothers and Babies in the period from

1937 to 1947 are reported. These cases agree both in symptoms and in progress with those reported in other clinics. They bear out the description of symptoms and the results of treatment that have been put forward in the literature. However there are several interesting features.

In cases 1 and 3 hysterectomy had been performed 10 and 11 years earlier respectively. All patients had had large families, and in all there was some degree of prolapse or of gaping of the introitus. The patient in case 4 had complete proctostoma. Her case was interesting in view of the fact that although she had a large growth and had removed and resorted the pessary every 24 hours, symptoms had been present for only 3 weeks. Except in case 1 in which the patient complained of vaginal hemorrhage and discharge of 4 years' duration, the history was of short duration. Radiation treatment was the only type used, probably because the patients were elderly and in poor physical condition and radical surgery was impossible. In case 3 evidence of recurrence was shown 3½ years after treatment. All the other patients are dead. In case 1 recurrence took place in 6 months in case 2 in 7 months, and in case 4, in 4 months. CHARLES BARNY, M.D.

Sarcoma Botryoides Vaginae. Complete Excision of the Tumor in an Infant by the Combined Abdominal and Perineal Approach. HOWARD C. FLETCHER and STUART H. QUAM. *Surf. Clin. N. America*, 1947 7 240.

The authors state that this lesion is rare, the rate of its occurrence being one in every 4,000 gynecological admissions. Despite early diagnosis, the prognosis is very poor. This is especially true of the botryoid tumor of infancy and early childhood.

McFarland in 1935 reported 164 cases of vaginal sarcomas, of which 74 were botryoides. All of the patients were under 22 years of age and 41 were children of 2 years or younger. Treatment consisted of surgical excision or radiation, or both. No authentic cures were reported.

These tumors arise beneath the vaginal epithelium and form proliferative, moist, friable growths which project into the vaginal lumen and present at the vulva. In 50 per cent of the cases they begin on the anterior vaginal wall.

The course is one of rapid extension beneath the mucous membrane with invasion of adjacent viscera, especially the bladder. Distant metastases are rare. Sepsis and urinary obstruction are the usual complications.

With the experience gained from the treatment of carcinoma of the cervix with radical surgery plus the utilization of the advancements made in anesthesiology, parenteral therapy and biotherapy it is now possible to remove the uterus and upper vaginal vault without harming the adjacent vital structures. It is also anatomically possible to remove safely the lower portion of the vagina by way of the perineum. With this in mind the authors suggest that sarcoma botryoides vaginae be treated by

complete removal of the vagina, with the use of a combined abdominal and perineal approach.

One case of sarcoma botryoides vaginae in a 26 months old female is reported. The child was treated by complete removal of the vagina, using the abdominoperineal approach. The operation was performed by Mjels. J ROBERT WILSON M.D.

Leucoplakia of the Vulva NORMAN F MILLER, MAY H. PARROTT, JOAN STRYKER, GARDNER M. RILEY and ARTHUR C. CURTIS. *Am J Obst* 1947 54 543.

The authors' interest in leucoplakia stems from two sources: first, an increasing awareness of the numerous shortcomings in the concept of the disease and its treatment and second leucoplakia appears to have considerable cancer potentiality and for this reason should serve as a fruitful field for the study of early development rate of growth and similar aspects of squamous cell carcinoma.

Since July 1931 153 patients with leucoplakia of the vulva have been processed through the University of Michigan Hospital Ann Arbor. Of these 143 were seen prior to July 1945 and were treated in the customary manner with everything from soothing lotions to surgery. These are called a prestudy group in contradistinction to a study group of 36 patients (11 new and 25 return cases) subjected to careful scrutiny and observation since January 1 1946. Such data as were obtained form the basis for this preliminary report.

Since the average age of women with leucoplakia of the vulva is 55 years it is not surprising that a reasonable number should present other evidence of organic disease. The authors were not impressed by any apparent relationship to the vulvar lesion in those patients with coexisting organic disease. There were no diabetics in their study group. The blood pressure determinations were not remarkable. Blood serology was negative in all but one instance. Urinalyses were negative in all but 4 patients 1 of these was found to have occasional glycosuria, while 3 others showed evidence of urinary tract infection.

In 24 patients complete blood studies were made. In 8 of these the blood was normal 10 showed evidence of infection as indicated by an increased sedimentation rate, toxic granulations, or an increased white count. The study indicated that the changes noted were due to infection elsewhere in the body. Two patients showed pernicious anemia and 3 revealed idiopathic hypochromic anemia a higher incidence than that normally expected. Minor blood abnormalities were noted in 2 patients.

A study of the vaginal secretions showed only 1 patient with active trichomonas vaginalis vaginitis. Fast cultures were positive in 3 patients but clinical evidence of yeast infection was not evident in any of them.

Psychiatric consultation was obtained on 32 of the study group. While emotional instability is likely to be a factor in aggravating and prolonging the pruritic phase of the disease the authors could not assign a cause and effect relationship.

Chronic irritation is thought to be a factor in leucoplakia of the mouth a lesion similar to that of the vulva, but the authors have not yet been able to evaluate its role as an etiologic factor in the vulvar lesion.

Twenty five of the group were studied with reference to allergic manifestation 14 (56%) had no allergic history or recognizable sensitivity 11 (44%) revealed an allergic background of variable severity and in 2 the pruritus was somewhat relieved after removal of the allergen.

Because of the hyperkeratoses noted in vitamin A deficiency, the possibility of leucoplakia being a nutritional disease was considered. Blood vitamin A determinations were made on 10 patients and in only 1 instance was the level below limits accepted as normal. Blood plasma ascorbic acid levels were determined for 22 patients and in 14 (63.5%) the levels were normal or above.

Gastric acidity was noted in 12 patients and 6 had no free acid. Of the latter 2 patients had pernicious anemia. Since 25 per cent of the population over 65 years of age is believed to have no free hydrochloric acid and since one half of the women studied in this series, on whom the test was made, did have free hydrochloric acid the importance of the relationship would seem to be minimized.

Estrogen deficiency as an etiologic factor is not borne out by the authors' studies. This view is further supported by the fact that leucoplakia may exist without improvement in young women during pregnancy when the estrogen levels are normally high. In order to explore further the possibility of hormonal imbalance, urinary female sex hormone determinations were carried out on 20 women in the series. The findings were not sufficiently unusual to be significant.

The authors have found no entirely satisfactory cure for leucoplakia of the vulva. Treatment continues to be largely empirical and is aimed at the relief of symptoms. While operation has not yet been deemed necessary in any of the 36 patients in the group studied the authors state that surgery does have a very real place in the management of malignancy of the vulva and for patients with proved carcinomatous change whether on a leucoplakic basis or not they strongly advocate radical excision including inguinal lymphadenectomy.

JOHN R. WOLFE M.D.

The Treatment of Carcinoma of the Vulva J. L. McKEIVY. *Am J Obst* 1947 54 626.

There is still considerable confusion as to the effectiveness of the various forms of therapy which are being advocated and used for vulvar carcinoma. The author suggests that those who have to deal with the problem must decide on some form of attack. In the present article the attempt is made to evaluate the results of such a decision at the University of Minnesota Medical School Minneapolis to compare the results of the presently used radical vulvectomy with other types of procedures previ-

ously used and to prevent what information has come from the material in regard to the further extension of the surgical attack.

The material represents all of the vulvar carcinomas seen from 1938 to the end of 1946 and is classified into two groups. Prior to September 1938 the 36 patients were treated by a wide variety of measures including simple vulvectomy, unilateral and bilateral superficial removal and both superficial and deep gland removal, x ray therapy to the groin or to the vulva (or both) and radium or radon application to the vulva or groin. No single stage radical vulvectomy was used. Therapy was standardized in 1938, radical vulvectomy being applied to 38 of 41 patients (90.5%). The radical vulvectomy under local anesthesia is described.

In the early group 5 patients are alive and free of tumor 5 years or more after treatment, an absolute cure rate of 39 per cent. In the second series, 4 are alive and well more than 5 years after operation and 18 are alive and free of tumor for from 2 to 59 months, which is a significant improvement.

The author discusses some of the problems of the treatment of carcinoma of the vulva. There has been sufficient experience with early tumors treated by methods other than radical vulvectomy to make it clear that minor procedures are not satisfactory. Local excision or local irradiation has no place in the treatment of early tumors. It seems clear that carcinoma of the vulva, particularly that of the labia majora, is a generalized disease and that the multiple nodules or recurrences are more often new areas of tumor than metastases or residual tumor from the main mass. To remove the vulva alone is to fail to take advantage of perhaps the most important clinical feature of the disease, which is the fact that lymphatic metastases tend to remain for reasonably long periods of time in the inguinal and femoral regions without spreading beyond these areas. The presence or absence of palpable glands is no useful criterion as to the presence or absence of tumor in these areas. Contralateral involvement is so well known that the bilateral removal of glands needs no support.

The author energetically opposes gland removal for biopsy. It serves no useful purpose since the glands are to be removed intact later. It involves opening into possible tumor-bearing tissue and it can make clean removal of the gland-bearing mass impossible.

Of the 38 patients treated by radical vulvectomy the deaths of 4 have been charged as postoperative deaths, a mortality rate of 10.5 per cent. The author assumes that the mortality rate would be considerably higher if the operations were extended to include removal of lymphatic structures along the femoral and iliac vessels within the pelvis.

In view of the fact that there were 3 deaths from embolism among all of the patients, consideration will have to be given to vein ligation at the time of radical vulvectomy. This has not yet been done.

MISCELLANEOUS

Studies on the Human Corpus Luteum. JON I. BREWER and HAROLD O. JONES. *Am. J. Obst. Gyn.* 54: 56

It is rather generally accepted that the life cycle of the human corpus luteum, the cycle of the endometrium, and the relationships of these two systems to one another are constant and are not subject to variations. During the active normal functional state, the authors believe that this is usually true. It is the purpose of the authors to demonstrate, and to discuss the clinical importance of a variability which does occur, however, in these two tissues and in their relationships during the regressive state principally near and just after the onset of menstruation each month. Endometrial studies are frequently made in an effort first, to determine the presence or absence of a corpus luteum, second, to estimate the functional capacity of the corpus luteum in preparing the endometrium for pregnancy, and third, to study corpus luteum activity in relation to abnormalities of the menstrual cycle. Without proper evaluation of the normal variations these clinical studies may be subject to misinterpretation.

The tissues for this study consist of the uterus with the endometrium and the corpus luteum in each instance. These surgical specimens were obtained from patients who had completely normal menstrual cycles and whose ages varied from 23 to 47 years. Three specimens obtained prior to the onset of menstruation were selected as representative of this period and 7 specimens removed from patients on their first day of menstruation are described and compared.

In the human corpus luteum degeneration of the granulosa lutein cells is first noted at from 4 to 6 days before the onset of menstruation (Brewer, 1942). This degeneration is a slow and gradual process and in its early phases can be a reversible reaction if pregnancy ensues. It is not a process that occurs suddenly at the onset of menstruation, and it does not typically involve all the cells of the granulosa lutein layer uniformly. The authors demonstrate variations in the histologic characteristics of the granulosa lutein cells in different corpora lutea and also in the same corpus luteum just prior to, and during the first day of menstruation. These variations represent normal differences in rate and extent of degeneration in these cells. Variations are also shown in secretory activity and in extent of desquamation in the different endometria and in different regions of the same endometrium just prior to and during the first day of normal menstruation.

Not only do these tissues vary among themselves but there is so much variation that an absolute constant pattern cannot be established. A study of the endometrium during this period in the cycle does not accurately reflect the histological picture of the corpus luteum. Similarly, the histologic study of the corpus luteum does not reflect the true state of the

endometrium. It is possible that during this phase of degeneration the histology of the *granulosa lutea* in cells may not reflect a true index of the degree of functional activity of the corpus luteum.

The observations reported have clinical as well as academic interest. Endometrial biopsies are being more and more frequently studied in endocrine and sterility problems. In the numerous reports the presence or absence of corpora lutea and the qualitative and quantitative functional capacities of the structures are estimated from the histology of the endometrium. On this basis clinical diagnoses are made and treatments instituted. In order that errors may be avoided it is necessary that the histologic variations in the relationship between the corpus luteum and endometrium be evaluated. This is particularly true since it is rather universally advocated that endometrial biopsies should be taken on the first day of menstruation and it is at this time that the variations are greatest. Accurate interpretation of functional activity can be obtained only by studying the endometrium during the actively functioning period of life of the corpus luteum and endometrium. Biopsies therefore must be taken at least 4 to 6 days prior to menstruation.

JOHN R. WOLFF, M.D.

A Simple, Rapid Method of Approximate Dosage of the Gravid Gonadotropins in Daily Practice
(Su di un metodo semplice e rapido di dosaggio approssimato delle gonadotropine gravidiche nella pratica clinica corrente) AQUINO MARTO *Chir. ital.* 1946 48 125

Wishing to bring the brilliant theoretical studies of Simonnet and of Brindeau Hinglais (1932-1937) to a point where they would have some practical application the author first attempted to improve the Aschheim-Zondek test for pregnancy so as to render it less time-consuming and expensive for quantitative test purposes. The requirements with regard to experimental animals have been reduced to 2 rabbits and these need not be sexually mature (weight, 2 kgrs. or more). Not yet mature and light animals (body weight in one instance 1,340 gm.) may be used provided that a preliminary laparotomy and examination of the ovaries is done. Blood serum of the patient is used as it is believed to be more constant in its content of hormone than the urine and less toxic for the animal. The results are estimated on the basis of the rabbit unit of Brindeau and Hinglais which is defined as the smallest amount of hormone injected intravenously into the ear vein of a rabbit weighing 2 kgrs. that will exhibit at least one hemorrhagic point in at least one ovary within 48 hours. The proportion between the rabbit unit of Brindeau and Hinglais and the Aschheim Zondek unit averages about 7.5 to 10.

The technique varies of course, with regard to the information sought, and any number of rabbits are used if the test seems to need further clarification. An illustrative case would be that of a pregnancy which is suspected from the history and clinical findings of

degenerating into a hydatidiform mole. One cubic centimeter of the patient's blood serum is diluted with 50 c.c. of physiologic saline solution. One of the 2 rabbits is then injected with 1 c.c. of this dilution and the other with 0.5 c.c. If the reaction in both animals is negative the mole can be excluded. If the 1 c.c. test is positive, and the 0.5 c.c. is negative, a vesicular mole may be suspected however not a living mole. Of course on the basis of the test alone this might also mean other things such as a toxicity of pregnancy which also exhibits at times a moderately elevated hormone titer in the blood. If both tests are positive then the presence of a living developing mole is certain and the uterus must be emptied. Now to turn this into Brindeau Hinglais units (U.B.H.)—the 1 c.c. of serum (1/1000th of a liter) was diluted 30 times and therefore the 1 c.c. rabbit would, if positive have received at least 60,000 U.B.H. and the 0.5 c.c. rabbit at least 30,000 U.B.H.

This method has been, and is being widely and reliably employed in the laboratory at Verona. Its desirability in cases of malignant degeneration of chorioepithelioma, in which the hormone titer tends to be constantly high as a control for the indications for hysterectomy is evident however no instances of this malignant development have come to light during the 3 years of the author's incumbency. In one instance, however a chorioepithelioma could be excluded and the hysterectomy avoided.

JOHN W. BRENNAN, M.D.

A Correlation between Vaginal Smear and Tissue Diagnosis in 1,845 Operated Gynecologic Cases.
N. PAUL ISRAEL, JOHN F. JEWETT, MALCOLM S. ALLAN, and ARTHUR T. HERRIO *Am. J. Obst.* 1947 54 376

The vaginal smear as a means of detecting uterine malignancy has been well established by numerous reports, but there are none regarding its value in a hospital devoted exclusively to the care of gynecologic patients. Therefore it has been the purpose of this study first, to determine the relative value of the vaginal smear in the discovery of cancer as compared to cervical biopsy and curettage, secondly, it was desired to test the practicability of the method with reference to the amount of special training the pathologist and allied personnel would need and the time they would consume in reading the smears.

Vaginal smears were prepared and stained according to the technique of Papanicolaou and were obtained before vaginal examination was performed. All smears were interpreted by one of the authors who was in complete ignorance of the clinical history and the tissue diagnosis at the time of the reading. In all cases the first smear was recorded as either positive or negative. Such interpretation on any given case was the only one used for the purpose of this study irrespective of whether or not another observer agreed with this initial diagnosis. Every field on every slide was completely examined. In suggestive smears this was done under high power

magnification whereas it was possible to scan less suspicious smears with the low power objective using the high power only on questionable cells.

In 1,000 cases, comprising those in which the tissue diagnosis was unquestionable 60 malignancies of the uterus, cervix or vagina were encountered. In 40 patients with carcinoma of the cervix, 39 were found to have positive smears the smear was negative 1 patient representing an error of 2.5 per cent. In 18 malignancies of the uterus, 15 smears were positive and 3 were negative giving an error of 16.6 per cent. Two carcinomas of the vagina were encountered and both had positive smears with no error. The total error of positive cases called negative is 6.66 per cent. In the remaining 940 cases with negative tissue sections, there were 11 false positive vaginal smears an error of 1.17 per cent. The total combined error of false positive and false negative smears is thus 1.5 per cent.

A second group consisted of 4 cases in which the diagnosis might be at variance with that of other pathologists and is therefore considered equivocal. Eight positive and 5 negative smears were encountered in 3 carcinoma *in situ* of the cervix. Only 1 positive smear was found in 7 carcinomas *in situ* of the endometrium. Four positive smears were encountered in 13 questionable carcinoma *in situ* of the cervix. No positive smear was found in 8 questionable carcinoma *in situ* of the endometrium.

The third group contains 4 cases in which malignancies were encountered elsewhere than in the uterus, cervix, or vagina. These incidental malignancies

are not included with the others because their diagnoses do not seem to be applicable to the vaginal smear technique.

From their results, the authors concluded that the vaginal smear method is an accurate and reliable adjunct to a gynecologic clinic. Since the method is actually applied daily would undoubtedly provide the observer with clinical information which the authors purposely avoided its accuracy could be reasonably expected to increase, largely by the avoidance of false positive readings. It is further significant that only one of the four false negative readings occurred because malignant cells were initially unrecognized although present, hence the other three have been repeatedly re-examined without the discovery of malignant cells, thus indicating an irreducible error inherent in the method.

Each of the examiners, previously experienced in tissue diagnosis, after studying the available literature, spent about 3 weeks under intense training in the vaginal smear method. The time consumed in reading varied tremendously and the process itself was much longer and far more tedious than the corresponding tissue examination. It is roughly estimated that average smears required from 15 to 20 minutes apiece, while in some particularly difficult smears it would require up to 2 hours; however, a second smear might not be as difficult as the first.

The authors note that the method proved most perfectly valuable in the study of early carcinoma and carcinoma *in situ* as well as in the diagnosis of more advanced cases.

JOHN R. WORTH, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

The Treatment of Eclampsia and Pre-Eclampsia with Veratrum Veride and Magnesium Sulfate
FREDERICK C. IRVING. *Am J Obst.*, 1947 54 731

Thirty years ago the delivery of an eclamptic presented no problem to the obstetrician. According to his simple philosophy the woman was having fits because she was pregnant, and if she ceased to be pregnant there would be no reason for her to have fits. Therefore he emptied her uterus forthwith usually by manual dilatation of the cervix followed by forceps or by version and extraction. About 30 per cent of the patients died usually from shock and hemorrhage. As cesarean sections became more common they were performed on eclamptics but with even worse results for the death rate then rose to 40 per cent.

In the middle 1920's a change from radicalism to conservatism began with the reports of Stroganoff and Lazard each of whom described the control of convulsions without active immediate interference the former using morphine, chloral and chloroform while the latter introduced the intravenous use of magnesium sulfate. In 1935 Bryant and in 1940 Bryant and Fleming reported the use of veratrum veride and magnesium sulfate in the treatment of eclampsia. Their results in two large series of cases were so much better than any published in America that the Boston Lying In Hospital decided to adopt Bryant's program. It is with the outcome of their series of 33 cases that this paper is concerned.

The little known pharmacology of veratrum veride is discussed in detail.

The patient is placed in a quiet darkened room with a nurse in constant attendance. Morphine one-fourth grain demerol 100 mgm subcutaneously, or 3 drams of paraldehyde in 2 ounces of mineral oil are used to control restlessness but are not given routinely. Five minims of veratrine are given hypodermically on admission. Veratrine is repeated as necessary in 5 to 10 minute doses at 20 minute intervals to keep the blood pressure below 150 systolic and the pulse below 80 or in the event of a convulsion. Magnesium sulfate in 50 per cent solution is given intramuscularly into the buttocks 10 to 20 c.c. every 4 to 6 hours. To encourage urinary secretion 250 c.c. of 25 per cent glucose in buffered sterile water are given slowly every 4 hours if the patient is unconscious. If she is conscious it is given every 6 hours. In a few instances the author found the use of salt poor albumin in 50 gm doses to be followed by a marked increase in urinary output and the disappearance of edema. The results with plasma have not been so satisfactory. Enough parenteral fluid is given to prevent dehydration and not enough to cause edema. If the patient is conscious she is given 2000 to 3500 c.c. of water every 24 hours.

Pregnancy is terminated only after the convulsions have ceased and an interval of 24 to 72 hours has elapsed. If the cervix is partially effaced and dilated enough to admit one or more fingers the membranes are artificially ruptured. If not a Voorhes bag is introduced. Cesarean sections are performed only on strictly obstetric indications such as cephalopelvic disproportion or placenta previa. Once induced labor is allowed to proceed normally and to terminate, if the presentation is vertex either by normal delivery or low forceps. Ether with oxygen is usually employed for normal deliveries and low spinal anesthesia for operative deliveries.

Thirty two patients with eclampsia were treated from 1940 to 1946 inclusive. There were 2 maternal deaths a mortality rate of 6.3 per cent. Both deaths occurred in neglected emergency cases admitted from small outside hospitals, both patients were moribund on entrance and died soon afterwards. The author states there is no cure for the grossly neglected eclamptic who arrives at the hospital breathing her last. The damage has already been done and nothing will save her life.

JOHN R. WOLFF, M.D.

Treatment of Placenta Previa. The Maternal and the Fetal Aspect. JOHN STURROCK, HUGH STIEL, IMA and ROBERT A. TENNENT. *Edinburgh M J* 1947 54-496

A review of cases of placenta previa observed in the Edinburgh Royal Maternity Hospital and the Simpson Memorial Pavilion of the Royal Infirmary Edinburgh during the years from 1926 to 1945 is given by STURROCK.

Table I compares the maternal and fetal mortality in the different 5 year periods. It shows a fall in the maternal mortality which is striking and a fall in the fetal mortality in the last two 5 year periods which is not so dramatic as the improvement in the maternal figures. Comparisons are then made of the results of the different methods of treatment in the various 5 year periods. After 1930 cesarean section became much more popular and was usually employed in most of the cases of placenta previa which were more than marginal in scope and in which the child was viable. Mere rupture of the membranes was generally used in cases of marginal or lateral placenta previa. In Edinburgh the use of Willet's forceps for scalp traction has remained quite popular as a substitute for bringing down a leg.

Since 1940 transfusion has been used much more frequently and apparently with good effect. The infection rate has also dropped as the years have passed, possibly through the use of the sulfonamides. Also since 1940 the policy of delaying active treatment has been employed more often with the hope of achieving maturity for the fetus. Because of this and the more frequent use of cesarean section the

TABLE I

Years	Numbers	Maternal deaths	Fetal deaths		
			Total	After 48th week	
		Per cent	Per cent	Per cent	
9	54	1.98	7.67		
10-20	68		20.98	29.12	32
21-30	209	7	12.67	63.12	63
31-40	70	0	12.29	25.71	26
41	18	8	12.5	20	7

fetal mortality has decreased considerably. However, delay is considered to carry certain added risks for the mother and is employed with some misgivings.

STIRLING reviews the cases of placenta previa admitted to the Glasgow Royal Maternity Hospital during the period from 1911 to 1946. He considers the maternal aspect of these cases. This series consisted of 55 cases, of which 222 were classed as mild (lateral) and 283 as severe (marginal complete, and central). Third stage complications were of frequent occurrence. There were 24 cases of postpartum hemorrhage in the mild group an incidence of 0.8 per cent, and only 8 cases in the severe group an incidence of 2.8 per cent. (The latter figure is explained by the fact that most of the patients with severe cases were treated by cesarean section.)

Blood transfusion was employed in 109 cases, i.e. in 21 per cent of the total series or in almost 30 per cent of the severe group alone.

There were 8 deaths, a mortality rate of 3.6 per cent. In the mild group (22 cases) there were 4 deaths 1.8 per cent mortality. In the severe group (283 cases) there were 14 deaths, 5 per cent mortality. Hemorrhage and shock occurred in 8 cases, and shock was due to postpartum hemorrhage in 3. 3 women died under anesthesia, on the operating table. In addition 1 woman died (undelivered) of acute cardiac failure and 1 died (undelivered) following an incompatible transfusion. Excluding all "non-notifiable" condition the morbidity rates were 0 per cent for the total series, 5.4 per cent for the mild group and 3.8 per cent for the severe group.

The results obtained with different methods of treatment were classified, and the following figures abstracted:

Mild Groups	Cases	Deaths	Per cent	Morbidity
N. treatment	20		66	5
V.B.M.	65		3	0
Packing	3			
Vernon	7			
Cesarean section	27			5

The question of delayed treatment was considered. If treatment was postponed for more than 24 hours it was considered delayed.

In general terms the figures appeared to show that some slight but definite added risk to the mother ensued when delay in treatment was adopted.

The fetal aspect of the same cases is given in TENNENT. There were 507 infants born in the case of placenta previa which Stirling discussed. Of these 334, or 65.9 per cent, left the hospital alive, 77.15 per cent, were stillborn and 66 or 18.9 per cent, died during the neonatal period. Thus, the combined stillbirth and neonatal death rate was 34.1 per cent.

In the cases of mild placenta previa 220 babies were born and 74.5 per cent of these survived. The corresponding figure for the 287 infants born in the severe group was 59.2 per cent. These figures supported the already well known fact that prematurity was the major danger to the infant in placenta previa.

Suggestions for decreasing the fetal mortality are:

1. Attempt to ensure that the infants attain a birth weight of 6 lbs.

2. Attempt to ensure the survival of the maximum number of infants born who weigh under 6 lbs.

3. Try to decrease the stillbirth rate.

The most noteworthy fact in the analysis is that in the cases of severe degree treated by cesarean section within 24 hours, 68 per cent of the infants left the hospital alive which was satisfactory.

The results in the cases in which cesarean section was delayed 24 hours or more were much less satisfactory.

The results were generally worse in the delayed group. It would therefore appear that to insist on delayed treatment on behalf of the child is a speculative procedure.

Conclusions. From the examination of these cases from both the maternal and fetal aspect, it was concluded that fetal survival appears no more certain in the delayed than in the immediate group, and as the maternal mortality and morbidity are slightly increased in the delayed group, delay in the treatment of placenta previa is not a justifiable procedure in the majority of cases.

The authors feel strongly while admitting the place of expectant treatment in placenta previa, that it should be reserved for elderly primigravidae and women with no living children.

DANIEL G. MONTOM, M.D.

Two Cases of Neurologic Affection Complicated by Pregnancy Diseminated Sclerosis; Myasthenia Gravis Pseudoparalytica (Zu zwei Fällen von affektion neurologische compliciert in gravidanza [Sclerosis plachbe—myasthenia grave pseudoparalytica]). L. BERNARDI GIAMAROLI. *Riv Ital gine.*, 1946, 29, 167.

Two instances of neurologic ailments complicating pregnancy although entirely different in most regards, are here reported together in order to illustrate the need for individualization in the prognosis and treatment of this type of patient. In both, the condition was rather recent in onset nevertheless complete examination and assessment could be accomplished before the initiation of the complicating

pregnancy. In both cases the patients had been pregnant for a period of about 2 months before coming under the author's care.

The patient with disseminated sclerosis was 21 years of age. She remained in excellent physical condition and it was decided to let her go on to delivery at term. The first stage of labor was somewhat prolonged however not longer than would be expected of a primiparous woman. A living child of more than 7 pounds body weight was born. During the later part of the pregnant period some edema developed about the involved extremities chiefly on the left side, and some evidence of involvement of the seventh cranial nerve was observed also a small pale area, not previously noted, appeared beside the papilla in the right eye. After delivery the edema largely cleared up and the other manifestations have remained stationary up to the end of the follow up period 4 months later.

The symptoms of the patient with myasthenia gravis became steadily worse following the onset of pregnancy she was absolutely bedfast and compelled to sit up in bed because of difficulty in breathing. A therapeutic abortion in the second month of pregnancy was decided upon. Following operation the patient has actually improved in the year since the operation she is now able to be up and about at her work part of the day and when at rest is able to lie flat in bed. The drugs usually employed in myasthenia gravis (prostigmine, strychnine) did not give the expected results, and this failure is ascribed by the author to the pluriglandular imbalances of the pregnant state. From this, then, the author goes on to speculate on the possibility that these imbalances may be at the root of the deleterious influence of pregnancy on these neurologic conditions.

JOHN W. BREKKE, M.D.

Myomatosis and Pregnancy (Míoma y embarazo)
C. COLMEIRO-LAFORET *Rev espal. obst.*, 1947 4
260.

Nine cases of pregnancy in myomatous uteri form the basis for this review of the subject. The youngest of the women was 20 years old. Seven delivered a living child spontaneously at term. The only mortality was that of 2 fetuses. In both instances hysterectomy was done one at 3 months for acute necrosis of one of the myomas and the other at 8 months in completing a cesarean section for retinitis albuminacea.

Since the author realized that definite conclusions are impossible with such meager material he studied the extensive material on this subject in the general medical literature. Even so the conclusions suggested cannot be taken too literally since the progress in obstetrical and surgical methods in the past few years has motivated a swing toward conservatism in the treatment of myomatous pregnant women and this has produced an improvement in the results however this improvement has not as yet become clearly defined. Then again the multiplicity of factors intervening in the diagnosis, rec-

ognition of complications, prognosis and treatment makes it extremely difficult to lay down any sort of general rules of procedure. The rare concurrence of myomatosis and pregnancy (in 0.5 per cent of all pregnancies) may be the result of some unfavorable influence on the fertility of the myomatous woman but it may also be due to the fact that the younger women with greater natural fertility do not tend to develop fibroids which would become of consequence in pregnancy. The tumors themselves may tend to grow rapidly during pregnancy or the rapid increase in size may be merely a passive increase due to the imbibition of more fluids from the enlarging and more succulent uterus itself. The tumors certainly tend to become softer and more yielding to the touch during the pregnancy and to regress and often disappear afterward. The fact that fibroids of the cervix or vaginal wall are so rarely of a size or in a location to cause dystocia may be explained by the fact that the uterine fundus has so much more muscular tissue to produce more and bigger tumors. The course of labor in the myomatous woman is certainly prolonged but it is not markedly longer than that in elderly primiparas in general. The presence of fibroids seldom exerts any decided effect on the position of the fetus in utero or even during labor. A large myoma may get in front of the presenting part and threaten to interfere with the descent, engagement or expulsion of the birth products; however, it happens that the foregoing tumor mass is expelled ahead of the presenting part or in its pliable resiliency slips back up into the uterine cavity and leaves the birth passages free. During this period rotation, necrosis and rupture of the myoma do not occur as often as the general instability of the uterine muscular walls in which it is immured would suggest. In fact, these complications—including the development of infection—occur much more frequently during the puerperium.

The one generalization which can be made with great certainty with reference to the treatment of these pregnant myomatous uteri is that they are a definite threat to the pregnant woman. She should be subjected to close and unremitting watchfulness. Placenta previa is disturbingly common in this condition and is probably to be explained on the basis of the changed nutritive or circulatory conditions over the area of implantation of the myoma. This either makes difficult the implantation of the placenta up in the fundus where the myoma is attached, or necessitates an enlarged area of implantation of this organ. The most constant early symptom of the degenerating myoma is the area of localized tenderness and pain.

Whether any one symptom or syndrome indicates surgical interference will depend upon a number of considerations but will in general not differ essentially from the indications such as similar obstructive or toxic processes of other nature. Many of these cases are successfully managed by conservative measures however if the tumor mass because of its

threat of obstructing the process of delivery or for other reasons, should seem to demand some active interference, cesarean section in the presence of a viable child seems to be the best answer. Even in the presence of a nonviable child the prospects for a successful myomectomy in the course of the pregnancy would not seem very good, since the incidence of abortion following these myomectomies is more than 1 in 3. If cesarean section is done it should not be completed by a myomectomy because the maternal mortality is from 12 to 25 per cent. If removal of the myoma seems necessary a hysterectomy should be chosen since the maternal mortality under these circumstances is not notably higher than that for the cesarean operation itself.

JOHN W. B. FROXY, M.D.

LABOR AND ITS COMPLICATIONS

Low Spinal Nupercaine Anesthesia in Obstetrics.
II. BERT E. SCHMITZ and GI. BABA. *Am J Obstet* 9:17-54, 1938.

The authors present the results of their study of 375 cases of low spinal anesthesia at Lewis Memorial Maternity Hospital, Chicago, Illinois. The patients were carefully evaluated as to contraindicating factors which the authors list.

The technique of administration is described as follows:

Small doses of hyperbaric nupercaine solution provided satisfactory analgesia of at least one hour's duration in 370 patients. Perineal anesthesia, percutaneous episiotomy and episiorrhaphy lasted on the average from 3 to 4 hours, but in a few cases was found to be present as long as from 7 to 10 hours. Recurrence of abdominal pain, however, appeared after 2 to 3 hours, and in some cases within 2 hours. Complementary and supplementary injections were

generally more effective in maintaining analgesia over a longer duration than the initial administration.

Hypotension requiring the use of ephedrine occurred in 13 patients, and in 2 of these "reactions" (hypotension, bradycardia, pallor, cold sweat, and fetal heart irregularity) developed which responded satisfactorily to the administration of oxygen and ephedrine. In all of the patients some motor excitement was present.

The area of anesthesia and hyperesthesia described a saddle pattern over the legs and perineum and extended over the abdomen to various segmental levels, for the most part below the level of the eleventh thoracic nerve. Blood loss at the time of delivery was usually small, but, as the minimal dose of nupercaine was not always used, no conclusions can be drawn.

In all cases but 6 the babies were awake, breathe, and cried as soon as the heads were delivered. There were 3 stillbirths. In 2 cases, the patient gave birth to twins, in each of which one twin was a macerated stillborn infant. In both of these cases the labor was premature. Fifty-two patients developed headaches on various days of the puerperium. A neurologic complication in the form of drop foot occurred once.

The authors conclude that low spinal anesthesia and analgesia is the anesthesia of choice in obstetrics. It is definitely satisfactory to the patient and her relatives, to the nursing staff, and to the obstetrician because of the dramatic and effective relief of the discomfort of labor, the maximum safety it provides the fetus and the mother, and the simplicity of the technique which utilizes a minimum of paraphernalia. It is imperative that the most careful technique be closely observed.

GENITOURINARY SURGERY

ADRENAL KIDNEY AND URETER

Adrenal Tumors and Pseudohermaphroditism: A Hormone Study of Cases. A. M. HAIN, J. POSE
Brit. Med. J. 1947 59 267

Progesterone, androgens and estrogens have been isolated from the adrenal cortex and recovered from the urine of persons suffering from abnormal function of the adrenal cortex. Androgen secretion is particularly increased in hyperplasia or neoplasia of the adrenal cortex giving rise to the clinical picture of virilism. The author confines himself in the present report to a study of adrenal cortical tumors and to patients with disordered cortical function occurring antenatally which affects sex development at the outset. He expects to report at a later date on the group which manifests some or all of the signs and symptoms of virilism after maturity (the adrenogenital syndrome). The group now described comprises male and female pseudohermaphrodites the former with the gonads of the male the latter with those of the female.

Since the clinical picture of virilism varies markedly in relation to the extent or type of the cortical lesion the author stresses the importance of hormonal studies of patients with symptoms of virilism. He reports in detail the method of Latterson and his associates (1942) for the estimation of 17 ketosteroids. With the use of this method in the cases of 6 patients with adrenal cortical tumor, he found a high androgen (17 ketosteroids) output in all but 1 patient, and an increased production of progesterone (pregnandiol) in some. In spite of the production and excretion of large amounts of ketosteroids and pregnandiol one patient in the series reconstructed four times during the last 8 months of life. While numerous reports of vaginal bleeding in children with adrenal tumors are recorded and in very hirsute women in whom marked adrenal hyperplasia was present, menstruation in adult women with adrenal tumors is exceedingly rare. The excretion of a pregnane derivative other than pregnandiol was noted in one of the patients in the present series as well as hypertension however the latter is said to be the rule in patients with adrenal cortical tumors or hyperplasia. As a result of the excess eosinophils observed in the histological sections of the pituitary in one case of adrenal cortical tumor the author suggests that adrenal hyperfunction can cause an excess of either the basophil or eosinophil cells of the pituitary gland.

Adrenal tumors or hyperplasia occur not infrequently in more than one member of a family. The occurrence of these tumors in the male is rare.

The author presents 8 cases of pseudohermaphroditism in which doubt existed at birth as to the correct sex of the infant. It is suggested that on the basis of the 17 ketosteroids in 6 of the 8 cases a

differential diagnosis between male and female pseudohermaphroditism might be made. In the latter hyperfunction of the adrenal cortex persists and is responsible for the condition manifesting itself in the excretion of excessive amounts of ketosteroids and sometimes pregnandiol. In the former on the other hand the ketosteroid output is either normal or slightly raised the condition having arisen and been completed antenatally.

The relationship between the hormonal output and the form of adrenal cortical abnormality as an aid in the differential diagnosis is discussed as well as antenatal sex alterations resulting from adrenal cortical changes. Hyperactivity of the androgenic function of the adrenal cortex both antenatally and postnatally has a profound influence on the sex characters of both sexes the tendency being a virilizing one in which the female characters are suppressed and the male accentuated. In cases in which male characters are weakened e.g. in male pseudohermaphrodites it is feasible to suppose that the androgenic function was either weak or late in being established.

PETER L. SCARDINO, M.D.

A New Operation for the Treatment of Hydronephrosis in Association with a Lower Polar (or Aberrant) Artery. H. HAMILTON STEWART. *Brit. J. Surg.* 1947 35 5

The author has always considered that the standard operation for hydronephrosis due to obstruction caused by a lower polar artery did not satisfy the ideals of surgery. If the vessel is large its division carries with it the dangers of infarction of the kidney with loss of tissue and the tendency toward infection. Imperfect drainage is another hazard with the risk of persistence of infection introduced through drainage tubes. Stenosis of the ureter with fistula formation may also occur.

Fig. 1. Diagram showing the changes in shape of the kidney and pelvic relationship which occur with growth.

Fig. 1 (Stewart) Photographs of clay models illustrating the apposition of the anterior surfaces of the poles of the kidney so that adhesions may develop over a broad surface and retain the kidney permanently in its new shape.

The author does not agree with the view of some surgeons that an aberrant artery is a minor factor in obstructions at the ureteropelvic junction and that a congenital stricture (or neuromuscular defect) at this point or elsewhere along the ureter plays an important part.

In the infant the kidney is arched upon itself to such an extent that the two poles approach each other closely over the enclosed pelvis. If a lower polar artery is present it will lie in close relation to the main renal artery and in this position it is unlikely to produce obstruction. As the kidney develops the poles diverge and the lower polar artery becomes separated from the renal artery and is capable of producing obstruction (Fig. 1).

The author has, therefore, devised an operative procedure in which he aims to re-establish the condition in the kidney present in infancy and since the artery is not divided and drainage tubes are not employed, to avoid many of the hazards of the older operations. The underlying principle of the operation is the molding of the kidney so that the lower polar artery shall come into close relationship with the renal artery. In this position the former is no longer capable of producing obstruction.

The pelvis and ureter are carefully dissected free from the lower polar vessels. The prolapsed pelvis is raised over the obstructing vessels and gentle traction is exerted on the ureter in its long axis to allow the pelvis to drain. If the hydronephrosis is large and the tension is considerable aspiration with a needle through relatively normal renal tissue is carried out. The capsule is reflected from the front of the upper and lower poles of the kidney and is left attached at the convex margin. The kidney is grasped in both hands and the upper and lower poles are brought together so that the kidney now approaches a ball in shape. Plain four-0 catgut sutures (about 5 in number) are now placed through the upper and lower lobes. Ribbon gut (hardened) is now threaded under the capsule along the new concave border of the newly shaped kidney like the rim around a wheel. The hoop of catgut is fixed to the

front with sutures. The tape must be perfectly flat. The plain catgut sutures are now tied lightly (Fig. 2).

The two pieces of reflected capsule are brought together and sutured. Traction is now placed on the long axis of the ureter and if dissection has been adequate the pelvis will come to lie mainly below the aberrant artery which should now lie in close proximity to the renal artery.

The pelvis is plicated at the front and back with interrupted to day six-0 catgut sutures, so placed that they do not pass into the lumen of the pelvis.

The kidney is replaced and the renal space is drained for 48 hours. Nephropexy is not performed.

The author has carried out this procedure in 15 cases with excellent results.

FREDERICK A. LLOYD, M.D.

Chorioepithelioma of the Kidney (Corioepithelioma del riñon) PEDRO MEL CARDOZA. *Boletín de Obstetricia*, 1947 9 9

A 41 year old white woman had delivered 9 healthy children and had had one abortion between the fourth and fifth normal pregnancies. The last pregnancy ended after 8 weeks with the expulsion of a hydatidiform mole. Two months later following an unsuccessful curettage for continued bleeding, a hysterectomy was done. In none of these operations was a histological study made. For 4½ years afterwards the patient remained perfectly well and without evidence of recurrence or metastasis. Then hematuria appeared a tumor of the right kidney was diagnosed, there were two Hoggren frog tests for chorioepithelioma both of which turned out strongly positive and nephrectomy was decided on.

The extirpated right kidney was about the size of normal, roughly globular or oval in shape and dark red in color. Despite the fact that most of the kidney tissue had been replaced by the new growth, the capsule was intact except for some nodules of tumor tissue protruding along the posterior border of the organ. Histologic study failed to disclose any evidence of normal kidney tissue except for a strip of uninvolved upper pole about an inch in width, where one normal calyx and the narrowly compressed kidney pelvis leading up to it were discerned. The rest of the mass showed extensive necrosis, hemorrhage and round cell infiltration which probably accounted for the tendency to felleble reaction in the patient. However, in well preserved areas the tumor structure was found to consist of a delicate connective tissue supporting structure extensive lacunae filled with blood and the characteristic parenchymatous structure consisting of irregular shapes and sizes of cells resembling Langhans cells, with abundant, pale, reticulated cytoplasm and large rounded nuclei with well defined nuclear membrane and granules of chromatin, and here and there a mitotic figure. There were also bands of deeply staining ill defined (syncytial) masses of cells with irregularly placed small, darkly staining nuclei.

The author believes that this tumor is an example of atypical chorioepithelioma, according to the origi-

nal classification of Marchand or a chorioncarcinoma according to Ewing. He believes that it arose as a metastasis from a chorionepithelioma of the uterus, or a dissemination of villi from the hydatidiform mole to the kidney which lay dormant for $4\frac{1}{2}$ years and then underwent malignant degeneration.

It is believed that nephrectomy was the only treatment indicated for this favorably located kidney tumor although it is admitted that irradiation therapy has given surprising results. A combination of surgery and irradiation for tumors of this nature which cannot be entirely removed surgically offers promise for the future. JOHN W. BRENNAN, M.D.

Ureteral Diverticulum ORMOND S. COLE, *J Urol.*, Balt. 1947 58 309.

The literature on ureteral diverticulum was reviewed and the author found that at least 7 types of ureteral anomalies have been erroneously reported in the past as ureteral diverticula. By using his criterion for the diagnosis of a true diverticulum (ovoid or round extraureteral congenital sacs which contain all the ureteral coats and communicate through a distinct stoma with the ureter) he was able to collect a total of 10 cases from the literature. Five additional cases were observed in which the diverticula were acquired following stricture, calculi and trauma.

In this condition there are no typical subjective or objective signs and there is no uniform positional distribution relative to the ureter or preference of side or sex. The treatment is dependent upon the immediate condition or location of the ureteral diverticulum, the ureter, the size of the diverticulum and the associated pathology. Surgical therapy may include ureteral reimplantation into the bladder end-to-end anastomosis of the ureter or nephroureterectomy.

An instance of left ureteral diverticulum of congenital origin in a 20 year old male is reported. Due to an associated hydronephrosis the patient was treated with nephroureterectomy with complete recovery.

The article is excellently illustrated and the 10 instances of congenital ureteral diverticula are tabulated. ROBERT LICH, JR., M.D.

BLADDER, URETHRA AND PENIS

Cancer of the Bladder BENJAMIN S. BARRINGER, *J Am Urol Ass.*, 1947 135 616

Barringer implants screened radon seeds by means of needles through the cystoscope or the cystostomy wound using radon seeds of 1.5 mc. about 0.75 cm apart, going to the edge of the tumor but not beyond. The greater the tumor induration the deeper the seeds are implanted. Bladder vault tumors are preferably removed by open excision. In small post-operative recurrences radium implantation should be employed but numerous closely placed seeds should be used. Tumors at the ureteral orifices should be treated exactly as if they were situated at any other area of the bladder.

The follow up treatment and handling of bladders which have had radium implantation often determines whether or not the tumor will be controlled. Other than radium therapy, operative tumor removal and total cystectomy are used for vesical tumors. Total cystectomy should be reserved for tumors which have many points of origin throughout the bladder, such as papillomas, papillary carcinomas, and infiltrating carcinomas. For the large single infiltrative cancers which occupy a large part of the bladder and extend down to the vesical base, Barringer doubts whether total cystectomy can result in more cures than can be obtained by any other method; such tumors are usually incurable by any known means. It is difficult to diagnose accurately vesical tumors from small specimens taken from the surface of the growth. When only a part of the tumor is obtained the pathologic diagnosis must be modified by the clinical observations to give the true diagnosis. In tumors graded in this fashion the percentage of 5 year cures of papillary cancers was 52 per cent and of infiltrating cancers, 23 per cent.

DAVID ROSENTHAL, M.D.

Lymphosarcoma of the Bladder G. E. MOLOVY, *Brit J Surg.* 1947 35 91

The author presented a rare case of lymphosarcoma of the urinary bladder in which the patient was subjected to transplantation of the ureters into the sigmoid and subsequent, total cystectomy. Three months later the patient died of rapidly spreading metastases.

Since the bladder has a rich network of lymphatics with some intercalated lymph nodes it is possible that the disease started in one of these nodes. The possibility of primary origin of lymphosarcoma in the bladder fits into the clinical and pathologic findings of the case described in this article.

The course of all types of sarcoma of the bladder after surgery is usually rapidly fatal. The only therapeutic hope lies in the early employment of radical surgery combined with irradiation. This is true in the cases of all lymphadenopathies. The results of excision combined or followed by irradiation of the primary lesion are far superior to those of conservative treatment or the single use of irradiation or surgery.

ROBERT TURKILL, M.D.

Total Cystectomy CHARLES C. HIGGINS, *J Am Urol Ass.* 1947 135 619

In the consideration of radical treatment for carcinoma of the bladder 4 surgical procedures for diversion of the urine are available: (1) ureterosigmoidostomy (2) nephrostomy (3) pyelostomy and (4) cutaneous ureterostomy. The latter is preferable if ureterosigmoidostomy is not done. Other factors to be considered in arriving at a decision whether or not to perform total cystectomy are early diagnosis, the results which might be secured by less radical types of treatment, the site of the lesion, whether one or both of the ureteral orifices are involved by the growth, gradation of the tumor.

Fig. (Stewart) Photographs of clay models illustrating the apposition of the anterior surfaces of the poles of the kidney so that obstructions may develop over broad surface and retain the kidney permanently in its new shape.

The author does not agree with the view of some surgeons that an aberrant artery is a minor factor in obstructions at the ureteropelvic junction and that a congenital stricture (or neuromuscular defect) at this point or elsewhere along the ureter plays an important part.

In the infant the kidney is arched upon itself to such an extent that the two poles approach each other closely over the enclosed pelvis. If a lower polar artery is present it will lie in close relation to the main renal artery and in this position it is unlikely to produce obstruction. As the kidney develops the poles diverge and the lower polar artery becomes separated from the renal artery and is capable of producing obstruction (Fig. 1).

The author has therefore devised an operative procedure in which he aims to re-establish the condition in the kidney present in infancy and, since the artery is not divided and drainage tubes are not employed to avoid many of the hazards of the older operations. The underlying principle of the operation is the molding of the kidney so that the lower polar artery shall come into close relationship with the renal artery. In this position the former is no longer capable of producing obstruction.

Total Cystectomy. CHARLES C. HIGGINS, *J Am Med Ass* 1947 135 619

In the consideration of radical treatment for carcinoma of the bladder 4 surgical procedures for diversion of the urine are available: (1) ureterosigmoidostomy, (2) nephrostomy, (3) pyelostomy and (4) cutaneous ureterostomy. The latter is preferable if ureterosigmoidostomy is not done. Other factors to be considered in arriving at a decision whether or not to perform total cystectomy are early diagnosis, the results which might be secured by less radical types of treatment, the site of the lesion, whether one or both of the ureteral orifices are involved by the growth, gradation of the tumor.

presence or absence of serious renal disease, and finally the age and general condition of the patient. In only 27.5 per cent of the author's series was complete excision possible without reimplantation of the ureter into another part of the bladder or without injury to the bladder neck. Many tumors are amenable to transurethral resection without or with radium seed implantation.

The mortality following total cystectomy is comparable to that in extensive operations for malignant lesions of the abdominal viscera. In many instances the poor end results are attributed to selection of cases. Abdominal exploration for metastases is routine. Higgins prefers primary transplantation of one ureter followed by secondary cystectomy and transplantation of the other ureter. In a younger person with good renal function a one-stage operation is performed. Abdominal excision suffices when the lesion is relatively far from the bladder neck; if the latter is involved abdominoperineal resection is used. Cystectomy and transplantation of the ureters into the rectosigmoid are now recommended under the following conditions:

1. No evidence of distant metastasis on abdominal exploration. Ureters too extensively involved that iliac nodes may be removed by block dissection.
2. The carcinoma is located on the floor of the bladder and the ureteral orifices are encroached upon, and the outlet of the bladder is so involved that if the cancer were to be locally treated by any method destructive action on the ureteral orifices, loss of vesical function and incontinence would result.
3. More extensive single or multiple infiltrating tumors are present.
4. Multiple recurring tumors develop rapidly and cannot be controlled by fulguration so that they eventually fill the bladder.
5. High grade malignant neoplasms are confined to the bladder.
6. It is obvious that renal function is adequate and distant or extensive local extension is absent.

DAVID ROXBOROUGH, M.D.

GENITAL ORGANS

Residual Prostatitis after Chemotherapy of Acute Gonorrhoea. F. C. BOURCAULT De COUDRA. *Brit M J* 1947 65

Subacute and chronic residual prostatitis are not uncommon sequelae of acute gonorrhoea treated with chemotherapy and/or antibiotics. The sequelae are symptomless signs including urethral discharge of a varying character, containing few pus cells with secondary organisms but no gonococci and with threads of mucus in the urine. The prostate is abnormal in size, shape, and consistency and, on massage, produces a pathological excess of pus cells without organisms. The author believes that the prostate should be evaluated by rectal palpation before starting treatment in cases of acute gonorrhoea.

Infection of the prostate apparently occurs very early in the course of the disease and may appear

clinically either before or after treatment when the gonococci have been destroyed. Prostatitis is more common than folliculitis which occurs characteristically in untreated gonorrhoea of at least 3 weeks duration, or in inadequately treated gonorrhoea, as with small infrequent doses of a sulfonamide. The urethral discharge of chronic anterior folliculitis or prostatitis is loaded with mixed organisms, and urethral smears show myriads of secondary organisms, usually small gram-negative bacilli. Such a picture never occurs in the urethral discharge associated with the prostatitis under consideration.

Evidence seems to indicate that the prostatitis in the present series is a true infection due to the invasion of the gland by the gonococci or other organisms or both. However such a conclusion fails to answer certain important questions:

1. Why the initially simultaneous development of anterior and posterior urethritis in some cases of acute gonorrhoea?
2. Why do a few gonococci survive penicillin, invade the prostate, and not the anterior urethra?
3. Why is the gonococcus so difficult to recover in cases of this kind? PETER L. SCARDON, M.D.

Some Aspects of the Surgical Pathology of the Testis. NORMAN WYNDHAM. *Austral N Zealand J Surg* 1947 17 47

The author outlines the embryological and anatomical steps of testicular descent. The gonad develops particularly from the caudal aspect of the intermediate cell mass low in the abdomen where it remains with little variation until migration to the scrotum occurs. From the anterolateral aspect of the intermediate cell mass the Wolffian duct develops. The latter becomes involved in the tail fold and therefore lies close to the cloaca with which it fuses in its posteromedial aspect. The Wolffian duct is connected to the groin by a fold of peritoneum, the gubernaculum, in which subsequently develops the gubernaculum. The latter lies near the developing testis, becoming attached to various areas but not to the gonad. It joins the structures of the cord at the junction of the vas deferens and epididymis. Muscular and vascular development actively proceeds and pushes the testis somewhat cephalically. Many fantastic theories have been proposed to explain testicular descent, yet little is known of the mechanisms involved. The gubernaculum could hardly pull by muscular contraction since either attachment is rigid. Apparently descent occurs quite rapidly during the seventh month without evidence of intermediate stages. It is interesting that one fails to find evidence of tension on the structures cephalic to the testes immediately following descent. Also, one notes a disappearance of the gubernaculum which would suggest that by shortening the testis would be pulled down, but this could only occur if the cephalic testicular attachments lengthened simultaneously. For this there is no good evidence. The stimulus to descent is derived from the pituitary gland acting on the testis itself.

There has been no entirely satisfactory explanation for the descent of the testis to the vulnerable scrotum. The phenomenon occurs in some, but not all, mammals. Testes destined to descend and which fail to do so do not develop normally. Imperfect development of the seminiferous tubules occurs with spermatogenesis arrested at the spermatid stage or earlier otherwise, however the misplaced testis functions normally. It has been stated that malignancy occurs more frequently in the testis which has not descended.

While the incidence of cryptorchidism is estimated to be about 2 per cent, a suggested figure for the occurrence of malignancy in undescended testes is 3.2 per cent. The author states that the majority of undescended testes will descend normally unaided but that the bilateral ones do not descend without assistance. While malignancy is known to develop in testes which have been transplanted to the scrotum the author condemns abdominal transplantation since tumors in such testes are difficult to diagnose.

Gonadotropic hormone of the pituitary is necessary for testicular development. However, the use of hormonal therapy in cryptorchidism has been disappointing. The author suggests the use of the hormone of pregnancy urine as an adjunct to surgery with the institution of therapy several weeks prior to orchidopexy.

The interstitial cells (Leydig) are said to produce androgens. However many conflicting observations have been reported and there exists no uniformity of opinion to explain the bizarre pictures observed in patients with testicular atrophy or tumors of the interstitial cells. Certain facts are fairly well established. The benign embryoma of the testis is not associated with any abnormal hormone production. While seminomas produce no hormone of their own by compression of the surrounding testis with atrophy of the interstitial tissue the pituitary gland produces sufficient follicularizing hormone to give an Ascheim Zondek reaction with a decreased androgen production. On the other hand adenocarcinoma and chorioepithelioma elaborate a lutenizing hormone.

The author observed 25 testicular tumors with an equal number of seminomas and teratomas but no interstitial cell tumors or adult embryomas. From his study he concluded that the prognosis depended on the inherent malignancy of the tumor and not on the length of preoperative history. Teratomas were not radiosensitive. While only 1 of 14 patients with seminomas were dead at the time of the present report 5 of 11 patients with teratomas were dead. Seminomas occur somewhat later in life than teratomas are radiosensitive do not elaborate hormones and the prognosis is better. Seminomas are said to be growths of the seminiferous tubules.

PETER L. SCARDINO M D

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Two Cases of Lipomatosis Involving Bone. S. F. OOSTHUIZEN and JAMES BARNETSON *Brit. J. Radiol.* 947 30 436.

Two cases of monstrous enlargement of the right foot in adults which existed since birth, were thoroughly studied by means of roentgenograms at the dissecting table, and by microscopic section after amputation of the involved extremity.

In both cases the primary changes appeared to have been marked infiltration and replacement of bone and soft tissue by "adult type" adipose tissue. There was also marked enlargement and distortion of the bones, and most of the joints of the involved areas were obliterated by bony ankylosis. There was, in one case, cross union between the phalanges. Round cell infiltration and great thickening of the small arteries were noted in both cases.

The etiology is unknown, but the authors regard the condition as a congenital disturbance of adipose tissue formation. NEWTON C. MEAD, M.D.

Cellular Mutability and Malignant Change of Cartilage Cells in Chondrodysostrophies (Instabilité cellulaire et déchéances de la cellule cartilagineuse des chondrodysostrophies) A. COMARACCO. *Lyon chir.* 947 4 48

The cartilaginous foci in Ollier's dyschondroplasia may ossify or remain indefinitely unchanged. The author discusses the possibility of malignant degeneration of these congenital cartilage cells. A possible slow malignant degeneration of large chondromas has been well known.

The exostoses found in Ollier's dyschondroplasia tend to ossify when the individual ceases to grow. Cases have been reported in the literature in which

exostoses have degenerated into malignant tumors. Most likely there was not a true cellular metastasis of bone cells into cartilage cells but an abnormal development of the enclosed cartilage cells into the exostoses. Ollier's dyschondroplasia has a tendency to ossify at termination of growth but there is no definite proof that the foci of cartilage cells invariably calcify. The ultimate fate of these cartilage enclosures is not known and the author presents a case of unilateral multiple enchondromas of the type of Ollier's dyschondroplasia which showed monstrous changes in several foci at the same time. The patient was a 12 year old boy who was admitted to the hospital with the complaint that several tumors had formed concomitantly in three different areas of the right arm. One tumor mass developed around the right elbow, one around the right shoulder and the third around the right wrist joint. There was local heat, pain and limitation of motion in the affected joints. Physical examination at time of admission showed discrete, hard, painful globular masses in the right shoulder involving the shoulder block the elbow and the distal third of the lower arm. The severity of the pain rendered the right arm useless. There was slight elevation of temperature (from 37.1 to 38.5 C.), severe anemia (0 million rbc) leukocytosis (12,200) and a normal white differential count. The roentgenogram of the forearm showed large well outlined cartilaginous masses in the central portion of the bones but with destruction of the cortex and invasion of the soft tissues at the periphery. The elbow joint also was partially destroyed by these masses. In the region of the shoulder the tumor mass had destroyed the joint completely and invaded the scapula. The distal end of the radius did not show as much destruction. The chondromatous masses were well localized in the cancellous portion of the bone. The periosteum was elevated along the entire diaphysis. The epiphysis was not disturbed. Biopsy of the tumors of the shoulder and elbow revealed small, well circumscribed cells with hyperchromatic, irregular nuclei within the marrow cavity. In certain areas the cells strongly resembled the picture of a spindle cell sarcoma. Giant cells were noticed especially around blood vessels. Biopsy of the regional lymph nodes revealed replacement of normal glandular tissue by fusiform cells with irregular dense, often monstrous, nuclei. The patient refused further treatment and did not return.

The question is raised whether one should consider this case as a true dysostrophy or whether one should assume that these tumors were malignant to begin with. The multiplicity of the lesions, their distribution and the age of the patient leave no doubt that this case originally was a dysostrophy. The malignant change in several foci at the same time points to a high degree of mutability of the cartilage cells in cases of chondrodysostrophy. Another proof of the

Fig. (Oosthuizen and Barnettson) The gross appearance of the foot in comparison with its fellow

considerable mutability of cartilage cells is found in cases of sarcomatous changes in Paget's osteitis deformans. In these of course, the change occurs slowly as a rule. Considering the mutability of cartilage cells in dystrophies, one is not surprised to hear of a case of enchondromas of the fingers which underwent malignant changes, metastasized and killed the patient within 2 months.

GEORGE I. REIMS, M.D.

The Cut Flexor Tendon J. B. KIMMORSE, *Brit J Surg* 1947 35 29

In this review of 31 repairs of flexor tendons in the hand the author states that he makes free use of the free graft and follows the teaching of Bunnell in the use of stainless steel wire which is removed sometime after the third postoperative week. He advises for this surgery a bloodless operative field, physiological skin incisions and extremely gentle handling of the tissues.

In the procedure to be followed primary suture should rarely be used and it never should be used when the tendon is severed within a sheath.

The majority of cut flexors should be dealt with by elective procedures after the wound has healed which in uncomplicated cases is usually about 3 weeks after injury.

A free graft of the palmaris longus tendon if this is available, is favored for all cases in which division has occurred within the sheath and both flexor tendons are removed from the tunnel even though the sublimis tendon is not injured. The proximal end of the graft extends to the middle of the palm so that the anastomosis will not be within the sheath. The distal end is attached to the distal phalanx.

A graft is not necessary when the severance has occurred so far distally that the tendon can be reattached to the distal phalanx without undue tension or when the division is in the midpalm and not within the tunnel.

Success is unlikely if there is pre-existing joint stiffness, or if the patient is aged. Unco-operative or unintelligent patients are not good subjects for this surgery as the postoperative care cannot be well carried out.

The technique of the operation is well described but it differs in no important way from the description of Bunnell. The stainless steel fixation stitch is removed in 3 weeks but active and passive motion of the fingers is not begun until 6 weeks postoperatively.

Of the 31 repairs described only 4 failed to give a result good enough for normal use and so that the patient could return to preaccident work. The author believes that 3 of these failures could have been avoided in the light of his present experience.

NEWTON C. MEAD, M.D.

Synovitis of the Wrist. THOMAS W. STEVENSON *Plast Reconstr Surg* 1947 3 443.

The gross anatomy of the tendons and sheaths about the wrist is reviewed briefly and the current

methods of treating synovitis are briefly discussed by the author.

Swelling and irritation of the synovial sheaths may be entirely mechanical and may be acute (due to unusual forceful use) or chronic (due to long repeated trauma). In the chronic condition a moderate effusion may persist and this may be accompanied by progressive thickening congestion and corrugation of the synovia. Sometimes villi are numerous and the lining of the sheath is reddish purple in color. The tendon itself may be enlarged and separated into several bundles with pale edematous almost cystic protruding masses. The tendon may even separate under continued stress. An illustrative case of this condition is presented. Cure was obtained by synovectomy.

Tuberculous tenosynovitis is discussed and the author presents 5 cases. The similarity of the chronic traumatic disease to tuberculous tenosynovitis, both in appearance and in the history obtained is mentioned. Synovectomy was carried out successfully and in one case resection of a metacarpophalangeal joint was done with good result.

An interesting case of a large lipoma located beneath the flexor tendons in the palm is shown. Such a lesion may simulate synovitis with effusion.

No controversial points are brought up in this article and no new methods are presented. It is well illustrated with good photographs.

NEWTON C. MEAD, M.D.

Posterior Displacement of Lumbar Vertebrae ABRAHAM MELAMED and DAVID J. ANFIELD *Am J Roentg* 1947 58 307

Posterior displacement of a lumbar vertebra sometimes referred to as reverse spondylolisthesis or spondylolisthesis posterior consists of backward displacement of the cephalad vertebra in relation to the adjacent caudad vertebra. The purposes of this study were (1) to ascertain whether or not the condition of posterior displacement of the fifth lumbar vertebra on the sacrum actually exists and if it does what anatomical factors are important for consideration (2) to determine what factors (anatomical, pathological, and/or technical) influence the roentgen appearance of the lumbar vertebrae and sacrum and (3) to determine the roentgen criteria of true posterior displacement of lumbar vertebrae.

A review of the available literature reveals divergent opinions as to the existence of posterior displacement of the lumbar vertebrae and explanations for the varied beliefs.

Specific anatomy of the lumbosacral spine is discussed. Attention is called to the fact that in the upper lumbar region the stress is downward and backward while in the lower lumbar region the stress is downward and forward. Usually the body of the fifth lumbar vertebra exhibits flaring or skirting at the posteroinferior margin. Slight rotation of the spine is found to exaggerate the actual extent of this condition.

Fig. 1. (Afekamed, Ansfield) Patient aged 60. a. Upright lateral roentgenogram in flexion shows posterior displacement of first lumbar vertebra on the second lumbar vertebra. Note marked narrowing of intervertebral space, verti-

cal and anteroposterior narrowing of the intervertebral foramina resulting in "hourglass" deformity of these structures, and overlapping of articular processes. b. In hyperextension there is increased retrodisplacement.

Fig. 2. Patient aged 50. Lateral roentgenogram reveals posterior displacement of fourth lumbar vertebra on the fifth. Reactive changes are quite marked and the intervertebral foramina show typical "hourglass" appearance. Widening of apophyseal joints (facets of anteroposterior type) well demonstrated (arrows).

True backward displacement of the lumbar vertebrae may be due to degenerative processes, disease, trauma, or congenital anomalies. Apparent backward displacement may be due to technical factors or to anatomical variations. The authors believe that intervertebral disc degeneration is the most common cause of the finding. This degeneration results in instability and relaxation of the longitudinal ligaments and secondary stretching of the capsules of the apophyseal joints.

Retrodisplacement occurs more frequently in the upper lumbar region than in the lower lumbar region because the upper half of the lumbar spine inclines backward in relation to the center of gravity. An important sign in roentgenography is designated as the "hourglass" appearance of the intervertebral foramina. This is noted on the lateral projection and is caused by a reduction in the distance between the posteroinferior border of the cephalad vertebra and the anterior border of the superior articular process of the caudad vertebra.

Displacements secondary to trauma, disease, and congenital anomalies are apparently much less frequent than those due to degeneration.

Apparent backward displacement of the lumbar vertebrae is relatively frequent according to the authors. This factor has led many critical observers to refute the possibility of actual retrodisplacement. Technical factors which can lead to errors in interpretation are faulty positioning of the patient on the roentgen table by disregard of the factors of rotation and sagging of the lumbar spine, incorrect alignment of the central ray to the structures in question, and

Fig. 3. (McLeland, Anfield) a Patient aged 19, student nurse. The transverse diameter of the pelvis measured 34 cm. while the transverse diameter at the waistline measured 36 cm. Lateral roentgenogram taken with hips elevated off table top for approximately 9 cm. in order to produce slight sagging in lower lumbar region. Note apparent narrowing of the lumbosacral joint and apparent posterior displacement of fifth lumbar vertebra. b Lateral roentgenogram of same patient, the hips no longer elevated and sagging eliminated, with central ray aimed at the lumbosacral junction. Neither retrodisplacement nor apparent narrowing of disc is observed.

short target-to-film distance. Anatomical and pathological factors which can account for apparent backward displacement are discrepancies between the midsagittal diameters of the fifth lumbar and first sacral segments flaring or skirting of the posteroinferior border of the fifth or last lumbar vertebra by peritrophic flapping of the posteroinferior margin of the cephalad vertebral body tapering of the vertebral bodies and sacralization of the last lumbar vertebra and beveled posterosuperior sacral margin.

Extensive studies are reported and illustrated showing varying roentgen appearances of anatomical specimens. In addition, careful evaluations have been made and demonstrated regarding clinical applications of these findings.

Criteria for the roentgen diagnosis of retrodisplacement of the lumbar vertebrae are elaborated in the article. They are as follows:

- 1 Degeneration of the intervertebral disc, with or without actual narrowing of the interspace (this is essential)
- 2 The posterior border as well as the anterior border of the cephalad vertebral body must be displaced posterior to the corresponding portion of the caudad vertebra

- 3 Narrowing of the intervertebral foramina—at least in the anteroposterior direction

- 4 Displacement of the facets and/or widening of the apophyseal joint space (this is believed to be essential)

- 5 Prominence or protrusion of the spinous process of the displaced vertebra on the sagittal projection

- 6 Alteration of the lumbar curve.

- 7 Roentgen signs of retrodisplacement not eliminated by technical means.

KENNETH H. SPONSTL, M.D.

Subcutaneous Tear of the Achilles Tendon. Diagnosis and Therapeutic Results (Subkutane Ruptur der Achillessehne. Diagnostik und Behandlungsergebnisse). OREHAM TOYOVAR. *Helvet. chir. acta* 1947 14, 209.

The clinical signs of subcutaneous tear of the Achilles tendon were first described by Ambrose Paré and Petit in 1772. It is a rare condition and therefore has been given very little attention in the medical literature. In a large European clinic only 17 cases were observed within a period of 20 years during which time 237 174 patients were treated.

This condition occurs quite frequently as an occupational disease in dancers, acrobats, and clowns. It is known in England under the name of "tennis leg" or "calf sprain." It occurs most frequently in men between the ages of 25 and 53. The lesion is usually unilateral. Familial occurrence was observed only once when a man sustained a tear of the Achilles tendon while playing handball and his sister sustained a similar injury a year later.

There is usually sharp pain in the region of the Achilles tendon as if it were struck by a whip (coup de fouet). After the lapse of a few days the pain is either localized further distally over the os calcis or further proximally over the musculotendinous junction of the calf muscles. The patients are unable to stand on their toes or lift their foot off the ground. Walking is difficult and associated with severe pain. Walking down stairs is especially difficult because of the unopposed action of the anterior leg muscles which tend to dorsiflex the foot.

The physical findings are characteristic. There is a depression of the skin covering the torn Achilles tendon when viewed from the side. The heel seems to be larger as compared with the normal side. In cases of incomplete tear there is a thinning of the tendon. Immediately following the injury there is a considerable hematoma due to the excellent blood supply in this region. In older cases there is atrophy of the calf muscles. This persists if patients are operated on at a late date. In some cases palpation with the fingers will reveal the gap in the tendon or the complete severance of the usually finger thick structure. By moving the foot up and down a tear in the Achilles tendon can be easily palpated. Usually a diagnosis can be made by means of a lateral roentgenogram taken with soft tissue technique. There is a depression of the soft tissue shadow of the tendon. Normally a triangle is seen on the roentgenogram, which is formed by the Achilles tendon, the calcaneus and the flexor digitorum longus, the flexor hallucis longus, and the peroneus brevis and longus. In case of a tear of the Achilles tendon this triangle is smaller and occasionally completely absent.

The tear usually occurs from 3 to 4 cm. proximal to the insertion of the tendon into the calcaneus, the tendon being narrowest at this level. There were 2 cases in which the tendon ruptured at two points.

Several conditions must be taken into consideration in the diagnosis of simple tear of the Achilles tendon such as fractures, sprains, and dislocations in the region of the ankle joint. Often the Achilles tendon tear is misdiagnosed as stenosing tenosynovitis, peritendinitis, achillobodynia, traumatic tendinitis, or rheumatism.

It is believed that prior to the tear some type of degeneration has to take place within the tendon. This is difficult to evaluate because by the time the patients are treated operatively it is not easy to differentiate degenerative and regenerative processes. It is impossible to state to what degree age infectious diseases or metabolic disorders may cause a

rupture of the Achilles tendon. It is quite likely that the mechanism of the Achilles tendon tear can be compared with that of patellar fracture, and that other conditions, such as syphilis, malaria, gout and gonorrhea represent only coincidental findings.

Conservative symptomatic treatment of the condition is not satisfactory and should be used only in cases of partial tear of the Achilles tendon at the musculotendinous junction. The patients suffer discomfort and are unable to walk without a limp for months and sometimes years after conservative treatment.

The sooner after the injury that operative treatment can be carried out the better the results. With the patient in the prone position the Achilles tendon is exposed and approximated with the help of 3 to 5 strands of braided silk sutures. In older cases it is often difficult to pull downward the proximal portion which has retracted upward for quite a distance. If approximation cannot be accomplished by the usual methods the following procedures may be employed:

1. The tendon ends are approximated as far as possible with silk sutures and the gap is filled in with connective tissue which ultimately replaces the missing tendon piece satisfactorily.

2. A portion of the contralateral fascia lata is excised, rolled into a tube and sutured in such a way as to surround the torn ends of the tendon. The fascial transplant eventually assumes all the appearances of a true Achilles tendon.

3. A portion of the gastrocnemius fascia is folded distally. Its distal end being left attached and its proximal end is sutured inside out to the calcaneus. The results of this procedure have not been entirely satisfactory as there is a persistent weakness in the calf muscles.

4. Toygar performs a bilateral tenoplastic operation by sliding a small portion of the tendon down or up respectively, to the gap and suturing it. The foot and lower leg is immobilized in a slight equinovarus position for 14 days. The plaster cast is then changed and the foot flexed to a right angle. Immobilization is continued for from 4 to 6 weeks, after which time physical therapy is given. The results have been uniformly satisfactory. Sixteen patients were treated operatively following the outlined procedure and were able to run without difficulty from 23 to 63 days postoperatively.

ORTHOPEDICS IN GENERAL

A Universal Splint for Immobilization of the Hand in the Position of Function. HARTY S. AILEY and MICHAEL L. MAROX. *Q. Bull. Northwest. Univ. Med. School* 1947 21 18.

The restoration of function is the main purpose of the universal splint described by the authors. The splint was devised during the latter phase of the Italian campaign. It is applicable in about 90 per

SURGERY OF THE BONES JOINTS MUSCLES TENDONS

Fig 1 (Mason and Allen)

cent of all wounds of the hand. It is made so that the cup holds the wrist in dorsiflexion and about the cup the fingers and thumb fall naturally into the grasping position. As the hand is laid on the splint and molded accurately to its surface fractures of the present, are reduced in the process by gentle pull on a strip of 2 inch adhesive tape. This splint is also useful in compression treatment of burns of the hand.

Most fractures of the metacarpals and phalanges may be reduced successfully by molding the hand over the splint and applying the compression dressing.

Oblique fractures through the proximal phalanges of the digits are treated successfully. The splint may be used for either the right or left hand and for maintaining the hand in the position of function in a wide variety of conditions. This splint is made up in 2 or 3 sizes and will meet the requirements of splinting in approximately 90 per cent of the cases.

RICHARD J. BENNETT JR. M.D.
The Walking Caliper JOHN CHARNLEY *Lancet* Lond.
1947 2 464

The art of making and fitting braces tends to be neglected by the younger generation of orthopedic surgeons. The commercial splintmaker perpetuates traditional types since he often lacks adequate professional guidance. The author made a study of the

walking caliper brace and developed a modification of the original type invented by H.O. Thomas. This modification was utilized as an easily fitted brace for use in the British army.

The fundamental principles for construction and use of the splint as invented by H.O. Thomas have been modified. Study of the literature and examination of a walking caliper brace originally fitted by Thomas have led to the following conclusions.

The authentic Thomas splints were of two types. The adapted bed splint was made from a bed splint by cutting off its end and inserting the splint into the heel of the boot. The ring was a simple ovoid the side bars were attached at opposite ends of the transverse diameter. The splint was thus symmetrical and reversible.

The Thomas caliper was described by the American surgeon John Ridlon in 1893 as follows. The ring is an irregular ovoid flattened in front, and drawn out at the posterior and inner portions. The ring slopes from without inward and from before backwards in such a way that the point upon which rests the tuber ischii is the lowest part of the ring.

In the caliper examined which was over 50 years old the side bars were in front of the transverse diameter the ring was flat in front, and the lowest part of the ring was posterior. With the side bars anterior in relation to the ring the bars roughly parallel the anatomical position of the femur.

Fig. 1. Ring of Thomas caliper and modifications thereof.

Proprietary rings are made with indentations or protrusions at the ischium in order to maintain position and weight bearing on the tuber. In practice this does not work out. The ring adjusts itself so that the lowest portion is under the tuber ischii. This gives rotation of the limb and/or pain. Indentations at the tuber ischii gives rise to displacement of the ring on contraction of the hamstring muscles. The author believes that the tuber ischii takes only a fraction of the body weight. A large part of the weight is efficiently taken on the ring through the fibrofatty fold of the buttock and the lower border of the gluteus maximus when in contraction.

Rings deviating from the Thomas type are the block leather ischial seat and ring, and partial rings. The block leather ring is a molded leather corset like that of an amputation prosthesis. It is dead, but is expensive and difficult to manufacture. The half ring is considered to be inferior in weight relieving

Fig. 2. Rings which deviate from Thomas pattern.

function, but is useful in paralytic cases. The author believes that the soft-front ring tends to encourage flexion of the hip and permits the ring to slip off the weight bearing surface posteriorly.

With all factors considered, the author designed the British Army adjustable caliper. Its purpose was to fulfill a need for a low cost, easily fitted, rigid type of brace for large numbers of patients. The ring is a simple ovoid and the essential feature is that the circumference can be adjusted to fit the root of the limb. The ring should be just snug enough to take some effort to pull to the root of the limb but should not be tight enough to constrict. Another factor the author finds advantageous is the placing of the side bars slightly behind the center of the ovoid ring for more direct lines of stress. An angle of about 30 degrees with the horizontal plane gives a good angle of inclination from the outer high side to the inner bar. The ring is best placed horizontally in the anteroposterior plane. The insertion of the caliper into the boot may vary anteriorly or posteriorly to the ankle joint axis. A stiff ankle brace is of the utmost importance in splinting delayed union of bones of the leg. Comfort may be obtained by raising the heel of the shoe on the normal side. Patients complaining of intolerable pain in the groin in the region of the adductor tendons will usually be found walking with the trunk sloping forward and with the hip in slight flexion.

KENNETH H. SPENCER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

The Necessity of Immediate Intervention in Phlebitis of the Inferior Vena Cava: a Case of Segmental Resection of the Vena Cava (Nécessité de l'intervention immédiate dans les phlébitides de la veine cave inférieure. Un cas de résection segmentaire de la veine cave) R. LERICHE, *Lyon chir* 1947 42 385.

In massive iliofemoral thrombophlebitis the thrombosis may extend into the vena cava despite symptomatic block and the use of heparin. Both lower extremities become swollen and the edema extends to the abdominal wall and lumbar region. Actually, the opposite iliac vein does not become thrombosed at first, despite the severe venous stasis. The author found undoubted liquid blood in the femoral vein 20 days after it had become obstructed by a thrombosis of the vena cava originating from the opposite side.

On the basis of 4 operative cases the author believes that vena cava thrombosis is probably always secondary to a thrombophlebitis of the iliofemoral system and is not primary in the vena cava itself.

Along with the inflammatory reaction in the veins there is a similar reaction in the vasa vasorum of the arteries which accompany the veins as well as a severe lymphangitis and lymphadenitis. In the chronic stage there is a marked perivascular fibrosis. Much of the edema in phlebitis may be attributed to lymph stasis.

The development of a collateral circulation begins promptly in these cases. The retroperitoneal veins are even more important as collateral channels than the veins visible on the abdomen. One case is cited in which one ovarian vein was as large as a loop of intestine. Despite the rich collateral circulation the patient with thrombosis of the vena cava becomes an invalid because of the pain, heaviness and swelling which occurred in the upright position.

The author reports a case of secondary thrombosis of the vena cava which arose from a postpartum left femoral thrombophlebitis. He operated on the twentieth day after the onset hoping to perform a thrombectomy of the vena cava. Because the thrombus was densely adherent, removal was not feasible; hence a segment of vena cava was resected between ligatures. Relief of symptoms occurred promptly after operation. Four months later the patient was almost completely free of the usual sequelae of vena cava thrombosis.

THEODORE B. MAMMILL, M.D.

Primary Septic Thrombophlebitis of the Inferior Vena Cava (Trombose séptica primitiva da veia inferior) A. MARQUES TORRES and NEIR A. MIRANDA. *Rev. Brasil med.*, 1947 4, 680.

When the authors first saw their patient, a man of 28 years, they thought that he had a syndrome of lumbosacral radiculitis involving L5, S1, and S2 with typical sciatica, which had started about a

month previously. The findings consisted of severe piercing paroxysmal superficial and deep pains which occurred spontaneously or were caused by movements of the spine or the extremities; pains which originated deeply in the abdomen and radiated around the trunk or along the extremities; nearly always bilaterally paresthesias which persisted during the recessions of pain; hyperesthesia of the lower third of the external aspect of the left leg; anesthesia and thermoanalgesia of the left foot; paresis of the left lower extremity with slight amyotrophy of the thigh; tendon reflexes first increased and then nearly abolished; trophic disturbances (edema, cyanosis); absence of sphincter disturbances; and spinal fluid with albumin at the threshold of normal (0.30 per cent) but without changes.

Because of the character of the persistent pains the second possibility considered was pelvic thrombophlebitis. Pott's disease, vertebral cancer, sacralization of the fifth lumbar vertebra, spondylosis and spondylitis, pachymeningitis, meningeal tumor, inflammation of the psoas muscle, and abscess of the iliac fossa were definitely excluded.

However 12 days after admission collateral circulation of the inferior vena cava type began to develop gradually without ascites and with slight edema of the abdominal wall. Edema was already marked in the extremities. A diagnosis of primary septic thrombophlebitis of the inferior vena cava was made. It was thought that it might have been due to infection of the genital organs as the patient had had gonorrhea with marked urethral stricture. The disease had probably developed as follows: genital infection of the urethra and prostate, pelvic cellulitis, involvement of the roots of L5, S1, and S2 by the inflammatory process and septic perithrombophlebitis of the inferior vena cava which, with progressive increase of the thrombus, culminated in the syndrome of portal hypertension. The patient died 9 days later and autopsy confirmed the diagnosis.

The authors call attention to the importance of gradual and unaccountable acceleration of the pulse for the diagnosis of inflammatory involvement of the venous system and to the fact that usually the disease begins with a small pulmonary embolism as occurred in the present case 3 days before the onset of the severe symptoms. Penicillin, sulfathiazole, sodium salicylate, iodide, and various analgesics were used in this case without results.

RICHARD KEMEL, M.D.

Experiences with Pulsating Hematoma W. C. BECK. *Am J Surg* 1947 73 580.

The author suggests that there has been a slight increase in the incidence of pulsating hematomas in World War II over that in World War I. This increase applies both to the actual incidence and the relative incidence as compared with arteriovenous fis-

tula. In the last war there was apparently about 1 pulsating hematoma to every 500 battle casualties. In all of the cases seen by the author there was partial transection of an artery which prevented the natural hemostatic sequelae of arterial transection from exerting their action i. e. retraction of the vessel with rolling up of the arterial intima.

In most instances there was however an attempt of the natural forces to stem the flow of blood usually by the interposition of a muscle plug. Then, when the extremity again was used and the blood pressure had regained its pretrauma level a secondary hemorrhage either into the tissues or through the original wound tract ensued. Thus most of the symptomatology was delayed for from 1 to 3 weeks, or longer following the original wound. Then secondary hemorrhage played an outstanding role. The differential diagnosis was generally not difficult if the lesion was kept in mind. The most important differentiation was from abscess because of the danger of an indiscriminate incision. This could easily be made with the stethoscope.

The more difficult differential diagnosis lay between pulsating hematoma and an arteriovenous fistula with a false aneurismal sac. The latter could be told by the to-and fro murmur and by the positive Brannham phenomenon.

There is little choice in the treatment. Of 24 cases observed as a result of battle wounds only 1 was observed to end in a spontaneous cure. In all of the others, an operative intervention became imperative, usually as an emergency procedure. A tourniquet was used whenever possible, and if this could not be done because of the position of the lesion, a provisional ligation of the vessel was done proximally. The approach to the vessel was found to be best through the classical approaches rather than through the presenting parts of the mass. A double ligation was necessary in each case and in none could any form of reparative surgery be performed upon the vessel.

Postoperative care was found to be most important in the care of the ischemic limb. Cooling of the extremity, as well as sympathetic denervation were found to be helpful. Of greatest importance, however was the replacement of lost blood through repeated and massive blood transfusion so that the

oxygen capacity of the blood was maintained at its maximum.

WILLIAM C. BECK, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

Lymph Leakage (Lymphorrhoea). F. C. FRANKLIN. *Surgery* 947 22 834.

The author reports 3 cases of lymph drainage from the site of operation following saphenous ligation.

It is amazing that lymph leakage should be so unusual a complication in view of the frequency of saphenous vein ligation, the propinquity of the subinguinal lymphatics and nodes to the saphenofemoral junction and the slow clotting of peripheral lymph.

The subinguinal nodes and superficial lymphatics coursing along the saphenous vein are those most likely to be torn in the dissection of the saphenofemoral junction. They are small, friable and lack the protective coloring of veins. Injury during operation is therefore usually unrecognized. Lymph flows more slowly than blood is lower in protein content and its viscosity is less than that of blood.

Howell has shown that delayed clotting is due to thromboplastic material. In the blood, this substance is contributed chiefly by the platelets and, to a minor degree by the leucocytes. In lymph, platelets are lacking and white cells are poor sources of thromboplastin. Howell also stated that lymph contained a relative excess of antithrombin. The delay in the clotting of lymph may be due to the low viscosity, lower protein content, lower fibrinogen content, lack of thromboplastin, excess of antithrombin, or more likely a combination of these factors.

In cases associated with phlebitis there is a great augmented flow of lymph which would tend to make this condition more persistent.

There are several effective means of treatment. The application of an elastic pressure bandage from the foot to above the incision with the elevation of the leg will invariably stop leakage within a short time due to the forcible collapse of the lymphatics. If the wound is laid open or disrupts, firm packing is advised. The local application of a thromboplastic substance is recommended as well. Drinker has suggested crushing the subcutaneous tissues with a hemostat to release an excess tissue extract rich in thromboplastic material. EDWARD R. DOWDNEY, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

The Value of Postoperative Dicoumarin Prophylaxis at Early Rising. SIO BORGSTRÖM. *Acta chir scand* 1947 96 47

Recent statistics indicate that both early postoperative ambulation and postoperative dicoumarin therapy decrease the incidence of postoperative thromboembolic complications by about one third. The question then arises as to whether a combination of the two forms of therapy will effect a further reduction in thromboembolic complications.

In an effort to answer this question all surgical patients over 25 years of age who were admitted to the Surgical Clinic in Lund during the year 1946 were divided alternately into two series. Patients in both series were allowed early postoperative ambulation and in addition the patients in one series were treated prophylactically with dicoumarin while those in the other series were used as controls. In approximately 17 per cent of the patients scheduled to have dicoumarin therapy, the surgeon believed it to be contraindicated and it was withheld. The author exhaustively demonstrates that the two series were comparable as to the average age of the patients, the duration of the time of stay in bed after operation, the body weight and the various types of operative measures carried out.

Dicoumarin therapy was started the day after operation when a dose of 0.25 to 0.125 gm was given. Further dosages were governed by the fall in prothrombin time which was kept between 60 to 40 per cent of normal. If bleeding occurred, or the prothrombin time fell below 40 per cent, vitamin K was given in amounts ranging from 0.5 mgm to 20 mgm. In the dicoumarin treated cases all postoperative bleeding was considered as due to the therapy, no fatal bleeding or any bleeding difficult to control resulted, and a percentage increase of bleeding in the dicoumarin treated patients of only 1.1 per cent resulted. The author thus concludes that properly controlled dicoumarin therapy is a safe procedure.

Upon analyzing the results the author found that among men no statistically significant decrease in thromboembolic complications was observed between the dicoumarin treated individuals and those in the control series. However in women there was a statistically significant decrease (of 4.4 per cent) in the incidence of these complications among the dicoumarin treated patients. Also no fatal pulmonary embolism occurred among the prophylactically treated patients, while 7 such deaths occurred among those not receiving this therapy.

The author thus concludes that combining dicoumarin prophylaxis with early ambulation does not decrease the incidence of thromboembolic compli-

cations in men but the incidence of such complications in women is definitely decreased.

F J LESEMAN JR. M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Essential Therapeutic Adjuncts in the Surgical Arrest of Wolff Israel Actinomycosis. MIMS GAGE, CHAMP LYONS, and PAUL T. DECAMP. *Ann Surg* 1947 126 368.

At the present time the management of serious actinomycotic infections has emphasized (1) antibacterial therapy, (2) high dietary intake of protein with adequate calories and (3) drainage of pus and surgical excision of tissue devitalized by infection. The authors add a fourth feature—transfusion of whole blood in quantities sufficient to restore the total circulating red blood cell mass to or slightly below the standard for the patient's standard or usual weight in health.

Most of the patients require radical surgical eradication of their disease. A poor tolerance for blood loss and surgical trauma has been encountered in these chronically ill patients.

Five patients with Wolff Israel actinomycosis presented themselves while the authors were making studies on hemoglobin deficiency in chronic shock and on the problems of reduced blood volume in the chronically ill patient. Observations of the quantity of blood necessary to overcome the anemia in patients with actinomycosis revealed an unexpectedly great deficit in the total circulating mass of red blood cells. The improved tolerance for surgical blood loss and the acceleration of wound healing noted after blood volume restoration were especially striking. Weight gain and convalescence were rapid in the patients with adequate dietary intake.

Secondary anemia and deficiency of body weight were characteristic features of this chronic illness. Laboratory estimations of the hemoglobin deficit were not too reliable when the hemoglobin concentration or hematocrit percentage was ascertained. The quantity of blood necessary to restore the hematocrit to the range of normal was in excess of that predictable on the basis of the initial hematocrit value.

The true deficiency of circulating red blood cells was more accurately revealed by blood volume determinations than any other available method. These measurements were performed by the plasma dye hematocrit method and standard values were calculated on the basis of the patient's usual weight in health. The results confirmed the existence of "chronic shock," the reduced blood volume being associated with weight loss (as described by Lyons *et al*).

The program of management of these cases was essentially (1) hospitalization (2) administration of

from 25,000 to 50,000 units of penicillin every 3 hours, (3) correction of anemia with blood transfusion to the point where the patient could tolerate surgical blood loss, (4) gain in weight, (5) surgery, (6) postoperative transfusions to prevent recurrence of "chronic shock" and loss of weight, and (7) administration of sulfa drugs for a prolonged period throughout the convalescence. Sulfonamides were not used preoperatively because of the depression of hematopoiesis, appetite, and synthesis of essential metabolites produced by the sulfa drug. Kidney complications were also deterrents in the use of these drugs while the patient was critically ill.

The authors' detection and correction of chronic shock in the treatment of actinomycosis have resulted in excellent results in the cases reported.

LUDWIG R. DOMOGUZZI, M.D.

Chemotherapy in Surgery. W. A. ALTMEIER, J. Missouri M. Assn. 947 44 803

Clinical experience has proved that for systemic administration, sulfadiazine is the least toxic of the sulfa drugs and the sulfonamide of choice in surgical infections. Experience has shown that the systemic or local use of sulfonamides will not prevent the development of local infection in a contaminated wound but it will keep an infection localized and thus prevent invasive infection. In penetrating wounds of the abdomen the prophylactic value of the sulfonamides has been amply demonstrated. The sulfonamides are of undoubted value in acute infections due to hemolytic streptococcus, the pneumococcus and the gonococcus but are of little or no value in infections due to the hemolytic staphylococcus. In certain mixed infections caused by both gram negative and positive organisms sulfadiazine has been of great value.

In contaminated wounds both the local and systemic use of penicillin, as with the sulfonamides, will not prevent the development of local infection but there is ample evidence that parenterally administered penicillin may attenuate, inhibit, or localize any infection that does develop within the wound. Penicillin is effective against the hemolytic staphylococcus and is the chemotherapeutic agent of choice in such infections. It is often most effective against sulfonamide resistant strains of streptococcus and gonococcus. Recently extremely large doses of penicillin have been utilized with encouraging results. Penicillin has greatly lowered the mortality of staphylococcal septicemia and its use in carbuncles may even abort the infection. It is an excellent agent in the management of acute osteomyelitis and its use in a series of 64 cases reduced the mortality rate to 15 per cent. Surgical intervention usually being unnecessary and abscess formation infrequent. Penicillin is very effective against aerobic hemolytic streptococcal infection, and in the treatment of an aerobic streptococcal infection penicillin is far superior to the sulfonamides. Penicillin is of but little value in tetanus and evidence indicates that the successful management of tetanus depends not on

chemotherapy but on early diagnosis, adequate chemotherapy and control of convulsions. Hemolytic infections respond well to penicillin therapy as does the form of rabbit fever caused by the *Streptococcus moniliformis*. Penicillin is by far the chemotherapeutic agent of choice in the treatment of pyogenic disease. Doses of 1,000,000 units every 3 hours is a valuable adjunct to proper surgery. Penicillin has been much more effective than the sulfonamides in the treatment of actinomycosis and probably the best results are obtained in this type of infection by combining these two chemotherapeutic agents.

In some respects the clinical effectiveness of streptomycin has been rather disappointing. Many acceptable pathogens rapidly develop high degrees of resistance and thus successful streptomycin therapy depends upon the use of sufficiently large doses from the beginning with early surgical drainage of abscesses before the development of resistance. Streptomycin is indicated in tularemia and bacteremia due to gram negative bacilli. Meningitis caused by *Haemophilus influenzae* and *Escherichia coli* responds to combined intramuscular and intrathecal use of streptomycin. This drug is of great immediate but often only temporary value in urinary infections. Liver abscess, cholangitis and secondary peritonitis also respond well.

The new agent, bacitracin gives considerable promise but its evaluation awaits further experimentation.

ANESTHESIA

Anesthesia for the Aged. JOHN B. DILLON, J. Am. M. Assn. 1947 35 977

At the Los Angeles County Hospital, Los Angeles, California, there has been a 60.1 per cent increase in the number of surgical treatments given patients 70 years of age and older in the past 10 years. The report deals with the administration of anesthetics to 900 patients over 70 years of age, during a period of 9 months. This geriatric group is analyzed statistically as to type of surgical treatment, the vital statistics including mortality studies.

The author discusses the anesthetic management of the aged patient through five general categories: (1) he stresses the importance of preoperative consideration of the patient to determine the anesthetic method best suited to him; (2) he emphasizes the importance of premedication keeping the drug dose minimal, and avoiding depression; (3) his discussion on the anesthetic agents and methods employed emphasizes also those methods and agents which should disturb the patient's physiology as little as possible; (4) operative care of the patient, particularly the use of blood and oxygen in the operating room, is essential if the patient is to have a maximum chance of recovery; (5) the immediate postoperative period is a critical one and proper care of these aged people and early mobilization is essential.

If these five factors are carefully considered and anesthesia is chosen on the basis of the patient's

physiology premedication is kept minimal and supportive therapy is used routinely then postoperative morbidity and mortality are more related to the effects of age and a preoperative pathologic state than to anesthesia and surgical treatment.

MARY KAUF M.D.
Anesthesiology 1947 8 453.

The analysis of the mechanism of anesthetic action began with the work of Overton. Meyer, and Traube each of whom attempted to correlate the anesthetic effectiveness of a wide range of substances with one or another of their physical properties. A second line of explanation of narcotic action initiated by Verwoerd, focused attention on chemical and metabolic relations. The chemical and physicochemical views are not mutually exclusive and the early work of Warburg soon brought them in fact, into a more comprehensive picture of narcotic action.

Recent work is directed overwhelmingly to a more precise analysis of the physicochemical mechanism of narcotic action and to the identification of the particular chemical links on which their action is manifested. Despite a number of specific negative findings there is a reasonably constant body of evidence indicating that narcotics do interfere with some link or other in the metabolic stream of non-ionic possibilities suggest both physical and chemical possibilities along the lines of the earlier theories.

The cytochrome system apparently is necessary and by careful exclusion narcotic action seems to be limited to cytochrome β or to an intervening flavoprotein. It remains possible, even in the enzyme experiments that narcotics inhibit the complete systems but not their fragments, by some relatively nonspecific physicochemical action rather than by blocking a particular postulated flavoprotein link. What the nature of such nonspecific action may be remains unknown, but many suggestions have been offered.

The author predicts that the use of electricity when more fully exploited will throw considerable light on the phenomena of depression and narcosis just as it has on the opposed phenomena of stimulation and excitation. Indeed the whole question of narcosis deserves careful consideration in relation to excitation for by whatever intermediate steps narcotics do interfere with mobilization of energy from the active membrane changes which are crucial to activity and activation. MARY FRANCES FOX, M.D.

Anaphylaxis and Anesthesia
Anesthesiology 1947 8 625.

A careful review of the literature on the protection afforded by ether anesthesia against anaphylactic shock shows evidence that is inconclusive and contradictory. The current study was undertaken in an attempt to determine whether ether does protect against anaphylaxis and also if such protection does exist, whether it is a property of anesthetic agents in

general. The method used was to induce anesthesia in experimental animals (mice and guinea pigs) without premedication. From the results of the study it was apparent that no generalizations could be made regarding the protection afforded against anaphylaxis by anesthesia.

Studies of two species reacting dissimilarly to the anaphylactogen indicate that the species peculiarities of anaphylactic shock so vary that any one anaphylaxis-inhibitory agent would fail to prevent the development of anaphylactic syndrome in all animals. In species developing bronchospasm as the primary manifestation of anaphylaxis cyclopropane anesthesia provides sufficient additive effect to accelerate the development of fatal spasm. It was concluded that ether anesthesia does not prevent anaphylactic shock in unpremedicated mice but actually enhances the manifestations of anaphylaxis and decreases the survival time following injection of the shocking dose of serum.

Cyclopropane anesthesia does not prevent anaphylactic shock in unpremedicated mice. However ether anesthesia in unpremedicated guinea pigs affords some protection against anaphylactic shock. Cyclopropane anesthesia does not prevent anaphylaxis in unpremedicated guinea pigs.

MARY KAUF M.D.
Pentothal Sodium Anesthesia in Poor Operative Risks. C. P. MARSH and M. H. RAMIREZ JAMES.
J. C. M. B. L. 1947 58 163.

This is a report of the use of intravenous pentothal sodium anesthesia in 155 patients on whom 96 major interventions on the genitourinary organs and 59 operations of short duration were carried out. There were no deaths or accidents. This is considered the method of choice for the poor cardiac risk and hypertension. It is followed by fewer complications and the renal secretion is unaffected during its administration. Anuria does not ensue. It is safe in the hands of the skilled anesthetist and when used on carefully selected patients. Recorded fatalities were due to improper selection of patients faulty technique, too high dosage and failure to supplement.

Further Studies on the Production of Cyclopropane-Epinephrine Tachycardia. J. W. STUTZ and QUINN MURPHY C. R. ALLEN and W. J. MERRILL.
Anesthesiology 1947 8 579.

This study was undertaken to determine the site of action of cyclopropane in sensitizing the site injected epinephrine. Since nembutal does not interfere with cyclopropane-epinephrine tachycardia this agent was used as the preliminary anesthetic for the procedures designed to eliminate cyclopropane from the cerebral or body circulation. The results of these experiments indicate that for the production of cyclopropane-epinephrine tachycardia cyclopropane and epinephrine do not have to reach the cerebral circulation but certain brain cen-

ters must be intact and functioning. Furthermore, the addition of cyclopropane to the cerebral circulation does not alter the duration of the cardiac irregularity. In view of these results and the fact that the cardiac sympathetics must be intact, it appears that the heart is reflexly sensitized by cyclopropane.

In an attempt to locate the afferent pathway of such a reflex the spinal cord was cut below the main cardiac sympathetic outflow. These experiments suggest that afferent impulses entering the cord below T 6 are involved in reflex cardiac sensitization.

The effect of excluding cyclopropane from the region innervated by these nerves was tested. The results indicate that cyclopropane stimulates receptors located in the mesentery or abdominal viscera distributed for the most part throughout the peripheral 3 cm. of mesentery. Impulses travel by visceral afferent fibers through the celiac and superior mesenteric plexuses, splanchnics, and spinal cord to a brain center above the pons. Efferent impulses then pass to the heart by way of the cardiac sympathetics and increase the irritability of the heart.

MARY FRANCES POZ, M.D.

Variations in the Signs of Acute Oxygen Want during Anesthesia. C. R. ALLEN, R. S. ECHOLS, E. A. HOFFMANN, K. C. O'NEAL, and H. C. SLOCUM. *Anesthesiology* 1947 8: 60

In the anesthetized or heavily medicated subject hypoxia or asphyxia may result in irreversible tissue damage or even death without the intervention of the usual warning signs of distress. The general signs and symptoms of hypoxia such as mental and sensory dullness, headache, and excitement are absent, and the signs that remain for the clinical anesthetist to consider are cyanosis, marked dilatation of the pupils, and variations in pulse rate, blood pressure, and respiration.

In the present report the respiratory and circulatory effects of hypoxia and asphyxia are studied in dogs which were under the influence of various anesthetic drugs. Seventy-five dogs were used. The effects of acute oxygen want were produced by having the dog breathe pure nitrogen or by allowing the animal to rebreathe the air from a one liter bag connected to an endotracheal tube through a carbon dioxide absorber. Asphyxia was produced by clamping the trachea or by rebreathing a one liter air sample without a carbon dioxide canister in the line. Blood oxygen and carbon dioxide combining power determinations were made preliminary to the experiments. Arterial blood pressure and venous pressure electrocardiograms, and stethocardiograms were recorded simultaneously.

Twelve dogs were used for unanesthetized controls. In the unanesthetized animal mild hypoxia resulted in an increase in respiratory volume, a change without change in blood pressure. More severe decrease of hypoxia caused a rise in blood pressure in addition to respiratory increase.

During the progressive increase in the degree of oxygen want three stages are defined. The pre-

crisis stage (when the inspired air contains 12.5 volumes per cent oxygen) which shows an increase in both rate and depth of respiration due to stimulation of the aortic and carotid bodies. In this stage the systolic pressure tends to increase and the diastolic remains unaltered, or slightly decreased. The increased heart rate and reduced peripheral resistance tends to increase the minute flow of blood through the body. The second stage occurs when the blood oxygen concentration is reduced to about 9 volumes per cent and circulatory crisis occurs. The heart begins to dilate and the systolic pressure begins to fall and bradycardia occurs. There is an increase in diastolic volume and the output of the heart increases. This is caused either by central hypoxia or by chemoreceptor reflexes and is mediated by the cardio-inhibitory nerves. There is a gradual fall of arterial pressure and a rise in venous pressure. In the latter part of this period the pulse rate gradually increases as the cardioinhibitory center loses its effect upon the heart because of central depression.

The third stage is a terminal one and occurs when the blood oxygen concentration has been reduced to 4 volumes per cent or less. There is a rapid fall of blood pressure and the terminal slowing of the pulse. The heart will stop immediately or go into ventricular fibrillation.

The slow bounding pulse of oxygen want did not occur in the experiments in which pentothal sodium, deep ether or nitrous oxide with premedication of morphine and atropine were used. When nitrous oxide and oxygen without premedication were used the vagal slowing occurred early in the period of asphyxia. With light ether and with surgical anesthesia in planes 2 and 3 of cyclopropane or chloroform marked periods of bradycardia occurred.

Arterial pressure rose in response to the central action of carbon dioxide in all the asphyxiated animals except those in which profound anesthesia was used. The blood pressure response to hypoxia was markedly reduced by sodium pentothal and by light ether anesthesia, and did not occur with deep anesthesia. An increase in respiratory rate and tidal volume occurred in response to asphyxia.

The danger of excessive premedication in an effort to employ smaller concentrations of anesthetic agents is stressed. The report primarily intends to be a reminder that the warning signs of asphyxia and hypoxia vary with the depth of anesthesia and with each drug employed. Attention is called to the fact that death from acute oxygen want may occur in the operating room without the patient evidencing such significant developments as a slow bounding pulse, a gradual arterial pressure fall or a period of "physiologic gasping."

MARY KARP, M.D.

Hydrogen Ion Concentration of the Spinal Fluid and Its Relation to Spinal Anesthetic Failure. ELLIS V. CORCORAN and RALPH T. KURTZ. *Anesthesiology* 1947 8: 594.

The authors report failure of the spinal anesthetic agent in 2 patients in whom extreme alkalinity of

the spinal fluid was present. The occasional failure to obtain analgesia even after repeated injections of spinal agents may be due to such a hydrogen ion concentration of the spinal fluid that precipitation of the drug as a base occurs. Experimental work was done to determine the upper pH limits above which the anesthetic agents would precipitate when mixed with solutions of cerebrospinal fluid. The drugs were:

- 1 Procaine—50 mgm. per cubic centimeter of 5 per cent glucose solution.
- 2 Nupercaine—1 mgm. per 15 cubic centimeter of 0.5 per cent saline solution
- 3 Pontocaine—5 mgm. per cubic centimeter of 5 per cent glucose solution
- 4 Lontocaine 1:1 with 3.3 mgm. per cubic centimeter of 3.3 per cent glucose and 16.6 mgm. of epinephrine per cubic centimeter
- 5 Alety—30 mgm. per cubic centimeter of Ringer's solution.

These mixtures of anesthetic agents were then mixed with normal spinal fluid in the ratio of 2 parts spinal fluid to 1 part agent mixture and the resultant pH was determined. They were then titrated with 0.05 normal sodium hydroxide until the first persistent cloudiness appeared.

From this work it became evident that as the pH of the spinal fluid rises slightly past the pH 8 many of the common spinal anesthetic agents are precipitated and become ineffective analgesic agents for intrathecal use. The normal range of pH of spinal fluid was determined on 50 consecutive cases from specimens taken preoperatively. The pH ranged from 7.35 to 7.70.

It was concluded that high alkalinity of spinal fluid is an occasional finding in certain patients and may be the cause of spinal anesthetic failure when other possibilities have been ruled out. It may actually be harmful to the patient to inject certain agents if high alkalinity is present for the insoluble crystals of anesthetic base may cause a nerve tissue irritation.

MARY KARP, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Preoperatively Applied, Mated Plaster of Paris Casts as an Aid in the Migration of Open Pedicle Cross Leg Flaps. RICHARD B. STARR, *Plast Reconstr Surg.*, 1947, 3: 433.

The most expedient and satisfactory method of covering foot and leg wounds which overlie bone or in which further underlying damage will necessitate the repair of bone, tendons, or nerves is the open moderately well standardized. The procedure has become after this migration the legs are immobilized in a variation of this procedure in the use of preoperatively applied mated plaster of Paris casts to facilitate and expedite the operation.

The advantages of preoperative application of the casts are that (1) casts can be carefully applied and

padded adequately (2) the operator's time is reduced (3) trauma to the pedicle flap is lessened (4) subsequent care is facilitated by windows cut in casts (5) with preoperative implantations of metallic holding devices into the casts they may be secured in position so that a sterile dressing may be applied. If a cast has to be applied postoperatively the flap must be kept in view thus inviting infection. In the 35 cases in which the pre-cast method was used no infections have developed.

The prep is done through the windows in either cast. The casts are draped by rolling them with two layers of sterile stockinette. LOUIS T. BYARS, M.D.

Metallic Sutures and Ligatures. W. WAYNE BARCOCK, *Surg Clin N America* 1947, 27: 1435.

The employment of metallic sutures and ligatures is not of recent origin and dates back to the ancient Greeks. In 1816 Hysnick suggested the use of lead wire sutures with which Mehtauer first successfully closed a vesicovaginal fistula in 1832. Later Sims was similarly successful with silver wire. A number of current reports indicate that the use of nonirritating metallic sutures for closure of wounds leads to superior results and permits the patient early ambulation more safely.

The author commenced using stainless steel wire in 1928 and since 1931 he and the surgical staff of Temple University have used a finer annealed alloy steel wire for sutures and ligatures in over 20,000 operations except for short periods when tantalum wire was substituted. Of 200 inguinal hernioplasties with an all wire technique only 1 wound infection occurred whereas there were 6 infections in a similar number in which catgut also was used. Among 1,000 abdominal operations in which closure of the wound was effected by wire alone only 1 wound separated but in a similar number in which catgut was introduced 7 suffered dehiscence.

Moreover studies on wound healing revealed that the lag period the delay before progressive union occurs is the result of irritating sutures. Catgut either plain or chromic, was found to be the greatest offender grossly in the formation of adhesions, and microscopically, in the production of inflammation and necrosis the extent varying directly with the amount used. Silk was less irritating but stainless steel wire caused little if any such sequelae.

Not only must metallic sutures and ligatures be strong flexible and practically inert in living tissues to avoid chemical or electrolytic reaction but they must not stain. Of the elements, only tantalum meets these requirements and of the alloys only stainless steel appears adaptable at present. The latter is so strong and resistant to chemical and thermal change as to be called the new noble metal. Tantalum wire does not possess the tensile strength which comparable soft annealed stainless steel wire does nor is it as smooth. It therefore does not slide so readily into a knot where it becomes more brittle and weaker. Moreover tantalum has a low resistance to heat and it is many times more expensive to

isolate and process into wire as compared with the alloy; however, it is more resistant to repeated flexions and extensions and may be preferable for buried continuous sutures.

The author and his staff prefer sutures and ligatures of stainless steel wire as well as plates of this alloy which are lighter and more adaptable at the time of operation. Neither metal when buried appears to be hazardous when the tissue is irradiated. It is prudent, however, not to expose large plates such as those used to fill skull defects to the hot sun or x rays for long periods.

The use of wire calls for special technique. Twisting leads to kinks and difficulty in the tying of knots and may be avoided by preparing sutures and ligatures in short butties of straight lengths. Clamping the end of the wire prevents injury to the hand or rubber glove. Only square knots should be used, these being tied best with the aid of a bismontat. A surgeon knifed or tied with one hand may slip and pull apart. The ends should be cut up on the knot to avoid projecting joint which if close to the surface may cause discomfort and may precipitate a law suit. When an exceptionally large number of arteries are to be ligated fine silk, cotton or nylon is preferred to gain more rapid and secure ligations.

For most operations 35 gauge for closure of the skin, fat, fascia and serosa, 32 gauge for suture of

the thinner aponeurosis, as in children, and 30 gauge wire for heavy fascial layers, muscle sheaths, and aponeurosis will suffice. Occasionally a 35 gauge suture with a very fine needle may be necessary for a divided nerve or a small tendon. Multifilament strands of wire may be used for continuous external since they withstand a greater number of bending movements; however, since they would appear to have a greater tendency to carry or hold infection along the suture tract than a plain wire, the monofilament is preferable as a buried suture in contaminated fields.

Among the many instances in which stainless steel sutures and ligatures have been employed to advantage by the author have been the repair of diaphragmatic hernias, external intestinal fistulas, vesicovaginal and rectovaginal fistulas, cleft lips and palates, perineorrhaphies, the one stage pull-through operation for rectosigmoid carcinoma, the reconstruction of the biliary and pancreatic ducts, and the approximation of the serosal layers when intestinal continuity has been restored.

Screens or cloth of fine annealed tantalum or stainless steel wire have been used to reinforce irradiated areas and to prevent the stretching of tissue. They have also been helpful in plastic surgery when the restoration and maintenance of a contour were necessary.

D. W. H. LYNN, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Symmetrical Calcification of the Cerebral Basal Ganglia. Its Roentgenologic Significance in the Diagnosis of Parathyroid Insufficiency
JONAS D. CAHILL *Radiology* 1937 49 568.

Twelve cases of symmetrical calcification of the cerebral basal ganglia in which there was definite clinical evidence of parathyroid insufficiency and tetany are presented. In addition the author briefly reviews the literature. The author briefly presents the roentgenographic picture of the diseases besides parathyroid insufficiency and other with this symmetrical calcification of the cerebral basal ganglia.

As early as 1855 Virchow observed calcification of the basal ganglia but not until quite recently has parathyroid insufficiency been associated with it. The pathological basis for the roentgenologic changes is a colloid deposition in and around the finer cerebral vessels with subsequent calcification of the deposits which coalesce and form vascular sheaths and concretions. These pathologic changes are most likely to be detected roentgenologically in parathyroid insufficiency and other diseases characterized by mental deterioration with or without convulsive seizures or motor symptoms referable to the extrapyramidal system. All of the 12 cases presented showed symptoms characteristic of parathyroid insufficiency namely cataracts, convulsions, mental retardation and trophic changes. The serum calcium in all 12 cases was below normal levels.

Roentgenographically symmetrical calcification of the cerebral basal ganglia is earliest seen as small irregular discrete, symmetrically distributed shadows of increased density in the region of the various basal ganglia, especially the putamen and caudate nucleus. As the masses of calcium coalesce the roentgen shadows become larger denser and more obvious. Coincident cerebellar calcification may be observed at any stage of the disease as well as evidence of calcification in the deeper layers of the cerebral cortex. These shadows should not be mistaken for evidence of neoplasm. The fact that the shadows are bilateral and symmetric helps to exclude the diagnosis of brain tumor. In case of doubt pneumographic studies will aid in the diagnosis. Calcification of the choroid plexus and this may simulate calcification of the basal ganglia. However calcification of the choroid plexus usually occurs in the region of the genu of the lateral ventricle and in the lateral view of the skull this region lies posterior to the basal ganglia.

Calcification of the cerebral basal ganglia can occur in diseases other than parathyroid insufficiency. It has been observed in patients with a previous history of encephalitis, tuberous sclerosis, toxoplas-

mosis and mental deficiency since birth. One case seen at the Mayo Clinic had no obvious cause for the calcification. In another case a mild hyperthyroidism and a positive Kahn test were the only clinical findings. Patients who give a history of previous encephalitis and have calcification of basal ganglia often show other discrete areas of calcification throughout the cerebrum. This is true also of patients with tuberous sclerosis. In toxoplasmosis the calcification in the basal ganglia occurs as large dense, irregular masses surpassing any changes observed in parathyroid deficiency. Here again other nodules of calcification are distributed throughout the cerebrum.

In conclusion the author emphasizes the importance of thinking of parathyroid insufficiency when ever symmetrical calcification of the basal ganglia is observed. It is possible that some cases of marked cerebral calcification associated with mental deterioration and convulsive seizures reported in the literature may have been due to parathyroid insufficiency. A serum calcium determination would have made the diagnosis. The response to adequate treatment in such cases, and the possibility thereby of salvaging an occasional mentally retarded or handicapped person or child justifies the search for parathyroid insufficiency in the presence of roentgenographic evidence of symmetrical calcification of the cerebral basal ganglia.

JONAS D. CAHILL M.D.

Roentgen Therapy in Chronic Mastitis GROVER E. PEAKLER and FLORENCE P. KERRICK. *Phyiotherapy* 1937 50 134.

Roentgen therapy in chronic mastitis is advised and justified according to the authors on the basis that practically all productive inflammatory or hyperplastic tissue when properly treated responds to a greater or lesser degree.

Chronic mastitis is a term applied to a condition of the breast characterized by pain and tenderness usually preceding the menstrual period and by a diffuse or localized nodularity of the breasts which is often bilateral and which most often affects the upper outer quadrant. A discharge from the nipple is at times associated with chronic productive mastitis and may be the only symptom. If the discharge is serous the condition is usually benign but if bloody the condition is frequently due to cancer. The technique used consists of from 4 to 6 treatments through a 6 by 8 cm. field usually beginning with the upper outer quadrant. The second treatment is given a week later from the opposite side of the breast. The third treatment is given a week later and then the fourth fifth and sixth treatments are given four weeks apart. Each treatment represents a 50 per cent erythema dose with high voltage rays. The authors use constant potential 180 kv. with 15 ma.

for 15 minutes, at 50 cm. distance and 0.5 mm. of copper which is 375 roentgens, or an equivalent dosage using 200 kv.

During the past 25 years 151 patients have been treated. Of these 111 were cured or markedly benefited, 25 were practically cured, 11 were benefited but had slight residual thickening and 4 showed no change. Of the 151 patients treated, 30 had local excisions of tumor tissue and of these 30 only 1 showed cancer. There were 4 patients in whom the thickened tissue persisted and mastectomy was insisted upon.

FRANK L. HUBERT, M.D.

Teleroentgenotherapy of Cancer of the Breast Especially in Inoperable Cases (De l'etion de la Teleroentherapie dans les cancers de sein et spécialement dans les formes inoperables) GARY D. LINT, Ed P. PILLON, *Pres. Med.* 947 57 641

The author states that total irradiation of a cancerous organism involves humoral reactions which produce variable results in the evolution of the tumor. Their recent experiences with the teleroentgenotherapy and semiteleroentgenotherapy of cancer of the breast led them to foresee some interesting possibilities of this method.

After a brief general review of the data published by various investigators on the total irradiation which is somewhat uncertain, the authors want to show by their precise clinical observation what one can expect from this method. Their technique uses 200 kv., 0.5 mm. copper F.S.D. 140 meter including all of the trunk when there are diffuse bony lesions, or 1 meter when there is a mammary lesion to be treated including the thorax only. The daily or 3 doses weekly vary from 25 to 75 roentgens per exposure according to the condition of the patient and tolerance used. The total dose varies from 150 to 750 roentgen per series of irradiation which may be repeated after from 3 to 6 months if necessary.

The effect on the bony metastatic lesions in 12 patients was as follows: 4 excellent results, 4 good results, and 4 mediocre results. The pain was rapidly relieved and the general condition was improved.

The effect on the pleuropulmonary metastatic lesions was not as good as the bony lesions. However there was a sedation of the cough, pain and dyspnea.

The effect on the tumor was as follows: (a) in 12 cases of scirrhus: 2 failures, 4 mediocre results and 6 excellent results; (b) in 4 cases of carcinomatous lymphangitis and perimammary infiltration: 1 great improvement and 3 mediocre results; (c) in 4 exophytic and ulcerated cases: 1 excellent and 3 mediocre results; and (d) in 8 cases with multiple local nodular lesions and adenopathies: great improvement in 4 cases and 4 mediocre results.

The authors state that teleroentgenotherapy has a particular mechanism of general action because the dose administered is not big enough to be cytolytic and this was confirmed by histological examination before and after treatment. The interrelationship of the hypophysis, thyroid and parathy-

roid may play a certain role. The influence of the ovaries has been mentioned also. The majority of patients irradiated on the trunk at 140 meters castrated in some time by this treatment. Those irradiated on the thorax are still menstruating. In general, better results are shown in patients past the menopause or in whom the menopause was induced.

The authors concluded that semiteleroentgenotherapy used with prudence is always harmless. The action of this treatment is still not understood entirely, but there is no doubt about its good general effect. It seems that one can expect more from it, and consider it on the level of local preoperative and postoperative radiation which permits the surgeon to remove the tumor in full quiescence, and the authors say that this is the treatment procedure they are using now.

MARC K. P. SUT, M.D.

Parallaxtic Fluoroscopy as an Aid in the Bronchoscopic Extraction of Foreign Bodies. (Gen. Weiden) *Acta radiol. Stockh.* 947 28 33

Fluoroscopy is valuable to the bronchoscopist in extracting radiopaque foreign bodies. The biplane fluoroscope has been advocated by Jackson and others; however this procedure requires considerable time. For this reason, the author has returned to the single plane fluoroscope. Under its control the bronchoscope can be guided to the foreign body. By moving the screen to and fro in a transverse position, a form of stereoptical impression is obtained. If the foreign body image moves more than the foramen, it is located dorsally; if it moves less, it is ventral. As both move together, the forceps are in the correct plane. Six cases of foreign body localization by means of fluoroscopic parallax are described in detail.

Transitory Focal Pulmonary Edema and Eosinophilia (Loeffler's Syndrome) ARTHUR T. HURD, GEORGE and CARLETON B. PEIRCE, *Int. J. Radiol.* 947 38 391

The authors describe a case which they classify as an example of Loeffler's syndrome in an allergic individual. In 1931 Loeffler of Zurich drew attention to a hitherto undifferentiated condition, not identifiable with any known disease and characterized by transitory roentgenological lung shadows and pronounced eosinophilia, with for the most part an extraordinary absence of symptoms and clinical signs. Fourteen of Loeffler's 51 cases were discovered accidentally. The patients had no complaints except that the majority did have the mild complaint of tiredness or fatigue. Slight cough was not unusual. Sputum, if any, occasionally showed eosinophils, never tubercle bacilli nor *Ascaris lumbricoides*. Characteristically the chest roentgenograms had pulmonary shadows of the nature of patch areas of increased density, which occurred in any pulmonary area and lasted from 7 to 30 days; they disappeared in one area to reappear in some other area. Concomitantly a pronounced increase in blood eosinophilia constitutes the third major feature of

the syndrome. The white blood cell count in Loeffler's series varied from normal to 15,000.

The authors' case was that of a patient whose personal and family history bore evidence of his allergic predisposition. The patient was sensitive to house dust and ragweed pollen and also exhibited evidence of bacterial allergy to the infecting organism namely the *Haemophilus influenzae* a constant finding in the sputum and infected sinuses. On readministration of specific vaccine for the *Haemophilus influenzae* he developed joint and muscle pain and fever and marked purpura of the Schoenlein type and during this episode there was transitory electrocardiographic evidence of a bundle branch lesion with subsequent normal tracings. This was considered evidence of vascular allergy. By the same token the transitory Loeffler shadows seen in the lung may with propriety be regarded as allergic edema involving the capillary network of the interalveolar tissues of the lung.

Roentgen Demonstration of Calcifications in the Interventricular Septum in Cases of Heart Block

FRANK WINDHOLZ and CHARLES GRAYSON
Am J Roentg 1947 58 411

Of a series of 61 patients who on roentgen study showed calcifications in the mitral annulus fibrosus in the aortic ring or in their valves, 12 suffered from heart block. In all the cases of heart block calcifications of the septum were associated with calcifications of the aortic or the mitral ring. The mitral ring was involved in 9 cases, the aortic valve in 3 cases. No calcified tricuspid rings were found in any cases. The location of the septum was correlated to that of the adjacent calcified ring or valves by using postmortem specimens of cases studied roentgenologically during life. In studying the relationship of the septum to the mitral and aortic rings the observations were made more precise by roentgenograms taken in typical projections of a heart specimen in which the rings were marked with a wire loop and the septum with a bit of wire fly screen. In this way not only the spatial interrelationship of the structures but also their overlapping and foreshortening in roentgen examinations could be demonstrated.

Three types of roentgen signs are recognized which are considered as indicative of the presence of calcareous deposits in the membranous septum:

1. Caudal extension of calcium shadows from calcified aortic valves or aortic ring.
2. Complete circular or crescent shaped calcifications about the mitral ostium.
3. Incomplete mitral ring calcifications with nodular thickenings of calcareous deposits at the right (medial) end of the posterior branch of the calcified mitral ring.

Roentgen signs of calcium deposits in the septum are, as a rule, associated with heart block or prolonged conduction time. At times calcifications can be demonstrated roentgenologically in the septum with no clinical or electrocardiographic signs of heart block.

X-Ray Signs of Altered Alimentary Function following Autonomic Blockade with Tetraethyl ammonium

JOHN F. HOLT, RICHARD H. LYONS, ROSALIE B. NALIGH, GORDON K. MOZ and FRED J. HODGES. *Radiology* 1947 49 603

Tetraethylammonium is a quaternary ammonium compound structurally similar to acetylcholine. Animal experimentation had shown that intravenous or intramuscular injection of the drug produced a rather specific blockade of the transmission of nerve impulses through the sympathetic and parasympathetic ganglia.

Clinical use showed that the drug produced widespread autonomic nervous system effects. Certain hypertensive subjects showed a significant drop in both systolic and diastolic pressure and in 1 such patient, who also had a duodenal ulcer, the ulcer pain stopped completely during the activity period of the drug.

The drug has relieved pain and increased temperatures in peripheral vascular diseases associated with vasoconstriction. It is a useful diagnostic tool in assaying sympathetic tone in candidates for lumbar sympathectomy. It appears of limited value in the symptomatic treatment of hypertension.

There was no effect upon the esophagus particularly in reference to the relief of cardiospasm.

The stomach promptly became atonic and remained quiet for the duration of the drug activity. The appearance was strikingly similar to that seen following vagotomy.

With intravenous administration there was a rather dramatic cessation of intestinal movements lasting for only a few minutes. Intramuscular injection produced similar changes which persisted for as long as 3 hours. The mucosal markings appeared to be fixed in one position. This did not occur in every case but it was too frequent to be coincidental. Meckel's immediately precipitated peristalsis. Atropine alone and adrenalin even in high doses never stopped peristalsis.

No appreciable change was noted in the colon although the bowel could be distended without producing a desire to defecate.

The drug should prove to be a useful agent in further investigation of both the normal and disordered autonomic nervous system.

J. P. TOMBULA, M.D.

Roentgenologic Aspects of the Chronic and Intermittent Varieties of the Transverse Axis Type of Volvulus of the Stomach

(Il quadro radiologico del volvolo gastrico sull'asse trasversale nelle sue varietà cronica e intermittente) MICHELE CESARINI. *Arch Ital mal app diger* 1947 13 249

Five cases of gastric volvulus on the transverse axis, that is the axis passing through the cardia and the pylorus, are reported. All of the patients were middle aged, 4 females and 1 male, and all had suffered from dyspepsia and epigastric pain. In 4 of these individuals the attacks had been intermittent and in 1 the gastric distress had been more or less

continuous resulting eventually in malnutrition and marked debility. In the 4 intermittent cases the volvulus was of the subcolic variety: the transverse colon passed above the kink in the stomach and the splenic flexure which, lying above and to the left of the cardia was markedly distended with gas, and pushed up and partially immobilized the left cupula of the diaphragm. In each of these patients the stomach showed a tendency to revert to its normal position and configuration after a few hours. In 1 case the correction of the abnormality was accompanied by the discharge of large quantities of gas from the anus. In another the volvulus recurred when the left colic flexure again developed gaseous distention. In the chronic case, in which the abnormal posture of the stomach could not be redressed e. g. by placing the patient horizontally on the right side, the colon was depressed down beneath the shadow of the stomach in a double barreled shotgun appearance and seemed bound in place by adhesions. In this instance also the spleen could neither be palpated nor demonstrated roentgenologically (ectopic spleen).

In every case the roentgenologic picture was the same: the opaque material would pass into the stomach from the esophagus downward and to the left through the fundus, and then upward and to the left into the dilated corpus and antrum which were lying far to the left, uncovering the pyloric region and duodenum. After the fundus, corpus, and antrum had filled, the shadow crossed over in front of the shadow of the fundus and continued downward and to the right to the pyloric region. The pylorus itself appeared to be drawn upward and to the left and to be increased in length.

The various theories of pathogenesis are discussed. In every case in this material the stomach when reduced hung lower than normal giving some support to the theory of the relaxation of its supporting ligaments. The relationship of the attacks to food taking suggests the importance of overloading and distention of the stomach and the possible significance of gaseous distention of the colon and of adhesions has already been alluded to. However the author gives the greatest attention to the question of the malposition of the spleen in these patients, and he believes that it is now incumbent on the roentgenologist to determine the incidence of splenic ectopy in this malady as a splenectomy may at times be indicated.

JOHN W. BRENNAN, M.D.

Malocclusion Deformities of the Greater Curvature of the Stomach MAURICE FELDMAN *Radiology* 94:7 49, 1952.

In the educational program now being conducted to make the general public cancer minded more and more "normal" variations will be encountered which must be differentiated from malignancy.

The author reports 9 cases presenting marked irregularities of the greater curvature of the stomach which imitated malignancy but which by gastroscopy and surgery and following a long period of

observations proved to be due to hypertrophic gastric rugae. In many of these cases the first roentgen impression was suggestive of carcinoma.

Great caution must be observed in the interpretation of mucosal abnormalities and filling defects in the greater curvature of the stomach, especially in those cases which present defects which do not conform to the usual disease pattern. Repeated roentgen studies combined with gastroscopic and clinical studies are essential.

Marked hypertrophic rugae are not ordinarily consistent with carcinoma; however such changes are present in Hodgkins' or lymphoblastoma disease and syphilis. Giant rugae are also seen in gastritis associated with peptic ulceration.

R. B. LEVIN, M.D.

The Role of the Radiologist in the Management of Patients with Intestinal Obstruction, with Special Reference to the Use of the Miller-Abbott Tube. ELLIS C. OSGOOD, *Radiology* 96:491 539.

The radiologist has become an important figure in the study of patients suspected of having intestinal obstruction. Often he is the second physician to see the patient, even before the patient is sent to the surgeon. For this reason he must be familiar with the physiological changes which take place following obstruction, and with the manner in which to make certain of the diagnosis and the location of the obstruction. He must take into consideration the history, as well as the clinical course and physical findings if he is to make the correct diagnosis at the earliest possible time. Often he cannot make a flat roentgen diagnosis of a definite obstruction but may be able to offer valuable confirmatory evidence as to the presence of distention and its possible cause. With the help of a barium enema and studies of the chest, as well as scout films of the abdomen, he may even be able to offer some idea as to etiology of the distention and as to whether it is of a mechanical or reflex nature. He may be of much help in choosing the course of treatment but the actual treatment must be decided upon by the surgeon.

The examination should consist of an anteroposterior Bucky film of the abdomen together with a comparable erect film and decubitus films in both lateral positions. If possible for the patient, fluoroscopy of the chest should be employed. The interpretation of these films should answer the following questions: (1) Is gas present in the intestine and in what portion? (2) Is it normal or pathological in amount? (3) Is it due to mechanical obstruction or reflex causes? (4) If obstruction is present, where is it? (5) If the distention is reflex is there anything to suggest the etiology?

The earliest sign of a small bowel obstruction is the finding in the survey film of the abdomen of a small segment of distended gut. One may see a kink or a so-called "hair pin" loop. Such an appearance may be present as early as 4 hours after the onset of symptoms. There is usually no fluid seen at this time. As

the obstruction persists the distended segment increases in length fluid appears and the coils of distended gut seem to lie horizontally in the abdomen to produce the stepladder appearance. The upper small intestine pattern may be fairly normal but the lower part of the small gut loses its markings and as the process progresses there is a gradual loss of all characteristic markings with a tendency of all the distended loops to look the same. The position of the loops in the abdomen may be of some help in determining the part involved. Distention of the colon is more easily identified by its position visible haustral marking fecal contents and the scarcity of small bowel gas. The latter condition depends on whether the ileocecal valve is patulous or not. If this valve is closed in cases of obstruction of the colon a closed loop obstruction occurs. It is in this type of case that the cecum becomes so tremendously distended that rupture of the cecum becomes a real danger. The exact location of the lesion in the colon may be determined by finding the point where there is an abrupt ending of the distention with no gas or not an abnormal amount beyond. In these cases the barium enema will help to locate the lesion exactly. Obstructive lesions just distal to or just proximal to the ileocecal valve may make the distinction between small bowel and large bowel obstruction very difficult. This is true especially of inflammatory lesions in this area.

Several points in differential diagnosis between obstruction as described and distention due to reflex origin are discussed. In cases of reflex distention both the small and large bowel are involved. The distention is less likely to be so uniform and there is an absence of a pattern suggesting continuity which is the rule in organic obstruction. Reflex ileus occurs in cases of pulmonary infection, gastrointestinal infection, cholecystitis and cholelithiasis, irritation of the peritoneum, renal stones, uremia, vascular accidents and many other acute and chronic conditions. All such conditions should be thought of and looked for in all cases of intestinal obstruction, especially in the cases without typical intestinal colic. In their presence the diagnosis must be proved by a barium enema or the passage of the Miller Abbott tube.

The Miller Abbott double lumen tube has many advantages in cases of intestinal obstruction. Suction can be applied which decompresses the bowel proximal to the obstruction, peristalsis then returns and the tube progresses. A normal segment of bowel is then available for the introduction of nourishment and fluids. The removal of the distention alone helps to prepare the patient for an operation and in cases in which the tube comes to a definite stand still the injection of a thin barium mixture through the distal lumen may help determine the exact point of obstruction as well as the nature of the lesion. Following the operation, the continued use of the tube in the intestine prevents distention, protects the suture line, and makes the convalescence smooth. In surgical procedures involving resection of the large bowel the prophylactic introduction of the tube has

proved of value. There are a few contraindications to its use. It must not be used in persons known to have or suspected of having strangulation or gangrene of the bowel if operation is thus delayed. The tube should not be used in obstructions of the large bowel. In these cases there is an increase of tonus of the terminal ileum which makes progress uncertain and delays entry of the tip into the cecum and the cecal contents are usually too grumose for aspiration through the tube. If the ileocecal valve is open and there is a reflux distention of the small bowel decompression may be an advantage while the patient is being prepared for operation. The author goes into minute detail describing the technique of the passing of the tube with the advice that the procedure be in the hands of a team well acquainted with the difficulties which may be encountered and the various ways of successfully overcoming them. He believes that the radiologist would do well to accept the responsibility of intubating the patients since it is often to his advantage in making the diagnosis and since he must be present to do the fluoroscopy. He must also limit the time of the fluoroscopic exposure as well as the number of films taken since the procedure may take several days. The patient is usually kept in the radiology department and is handy for the radiologist who probably has more time than the surgeon and a better idea as to how often and when to make the necessary exposures. The entire procedure requires study and experience to be done successfully and to furnish the most information in helping to locate the lesion and deciding when to operate. Persistence and patience and experience are most important and lack of these will result in failure to use a valuable adjunct in making a correct diagnosis.

During the period that the tube is progressing, the length passed is watched as well as the speed and the manner of movement. In cases of simple mechanical obstruction the progress of the tip of the tube is apt to be fairly rapid to the point of obstruction. In cases of reflex ileus it will be much slower but often will increase as the edema and distention of the gut are relieved. The balloon must be kept inflated and constant adequate suction maintained to keep the tube progressing. When the tip of the tube seems to be definitely stopped a thin barium mixture may be injected under fluoroscopic guidance in order to study that part of the gut. If distention is present in the intestine proximal to the tip and adequate suction has been maintained, one can be sure that there are other areas of obstruction distal to this point, or other complicating reflex factors such as a generalized peritonitis or other cause. The actual point of obstruction must be visualized by means of barium in order to rule out a paralytic ileus. Palpation and maneuvering of the patient are used to endeavor to make the head of the barium column advance. The obstruction may seem to be complete clinically but the barium may seem to advance intermittently with peristalsis and the presence of intestinal colic. In these cases removal of the tube or stopping of the suction will bring back active intestinal colic. This

is observed in cases of incomplete obstruction. In these cases the bowel just beyond the head of the barium should appear normal but if there are any pockets of distention or fluid one knows that there are other areas of obstruction more distally. Often in cases of complete obstruction the removal of the distention may so improve the condition of the intestine that the symptoms may entirely disappear and contemplated surgery be made unnecessary.

The author concludes that the use of the Miller Abbott tube is a very important adjunct in the correct diagnosis and treatment of intestinal obstruction, and he quotes statistics to show a marked overall decrease in the mortality rate in cases of intestinal obstruction of all types treated surgically and in which intubation with suction has been used in the treatment. A note of warning is sounded against the set routine use of an one procedure without sound clinical evaluation and judgment of the individual case. The author presents case histories to illustrate his own experiences.

This article is well worth close scrutiny and filing for future reference. PAUL H. SWITZER, M.D.

Malignant Tumors of the Small Intestine. HOWARD P. DOON. *Radiology* 94:7 49 44

Malignant tumors of the small intestine are being diagnosed with increasing frequency, mainly because of a more widespread use of serial roentgenography. As a rule lesions of the duodenum and upper jejunum are discovered during routine examinations of the stomach but those occurring below that level require a special technique which consists in the administration of a mixture of 4 ounces of barium sulfate and 8 ounces of water on the morning of the examination with the stomach empty. A preliminary fluoroscopic study of the esophagus and stomach is made and as much barium as possible is forced through into the duodenum so that this organ also is examined at the same time. Fluoroscopy of the small intestine is then carried out and supplemented with roentgenograms at 30 minute intervals until a complete emptying has taken place unless obstruction is present. Golden states that on damage results from the administration of barium sulfate by mouth. Since the contents of the small intestine remains fluid the barium can be removed by suction in case of obstruction.

The author's series of malignant tumors of the small intestine includes 52 cases. In 23 cases the tumor was located in the duodenum, in 16 cases, the jejunum and in 13 cases the ileum. The pathologic distribution was as follows:

	Duodenum	Jejunum	Ileum	Total
Carcinoma		9	4	13
Lymphosarcoma		3	4	7
Carcinoid			3	3
Leiomyoma				
Stenosis carcinoma				5

Grossly the tumors were of two types (1) the constricting type and (2) the fungating or polypoid type.

As a rule the clinical picture was characterized by a progressive loss of weight, the presence of varying degrees of anemia and a change of bowel habit leading not infrequently to acute obstruction. A palpable tumor was an important and significant finding.

The most important roentgen signs were a narrowing of the lumen of the bowel with dilatation proximal to it, and marginal or central filling defects associated with obliteration of the mucosal markings in the involved area.

Tumors of the duodenum. In the author's series 17 per cent of the tumors were in the superampullary portion, 61 per cent were in the perampullary portion, and 22 per cent in the infraampullary portion of the duodenum. Clinically tumors of the superampullary portion often presented symptoms of gastric obstruction. In the perampullary group the most common localizing sign was jaundice. There was no jaundice associated with the infraampullary tumors, but patients often vomited large amounts of bile. In about 50 per cent of all duodenal tumors a palpable mass was present. The roentgen signs were dependent upon the amount of deformity or obstruction of the duodenum. They varied from a regular constriction of the lumen to large filling defects. Reverse peristalsis, gastric retention, and secondary duodenal displacements were common. In 12 of the author's patients there were definite localizing defects. In 4 there were obstructive lesions with high-grade gastric retention, and various typical deformities were found. In 3 patients the findings were entirely negative, 2 patients were not examined roentgenologically.

Tumors of the jejunum and ileum. These tumors produced a similar clinical and roentgenological picture. The clinical syndrome was usually that of obstruction, produced either by gradual encroachment of the growing tumor on the bowel lumen or by intussusception. As the tumor became more obstructive, pain assumed a more prominent role in the picture. Nausea and vomiting were rather constant symptoms. The most significant finding was a palpable tumor or a sense of resistance without tenderness. Secondary anemia was the rule and the stool examinations usually remained positive for occult blood. The outstanding roentgen findings were partial or complete obstruction with dilatation of the proximal bowel and filling defects with mucosal alteration.

Lymphoblastoma. This type of tumor occurred most frequently in the ileum. Acute obstruction is uncommon since the invasion is intraluminal rather than intraluminal. For the same reason occult bleeding was found rarely. The characteristic roentgen signs were areas of narrowing and adjacent areas of dilatation with aneurysmlike appearance.

Carcinoid tumors. In the author's series these tumors were noted only in a few instances but the literature contains numerous reports of larger groups.

The case histories are presented on 1 patient with duodenal tumor, 4 patients with jejunal or ileal tumors, and 1 patient with lymphohistoma. Some very excellent roentgenograms are used for the purpose of illustration.

T. LECOTIA, M.D.

Roentgenological Examinations of Ileus. J. FRANK DARR. *Acta radiol.*, Stockholm, 1947, 28, 331.

The author presents the roentgenological findings of ileus. The forms of ileus are classified under mechanical ileus which includes simple obstruction from without incarceration under adhesions, internal hernias, volvulus and functional ileus which includes paralytic and parietic ileus, and ileus following neurovascular changes.

In simple obstruction the findings are those of gas and fluid collecting in varying amounts in the bowel. With horizontal rays hoop-shaped loops are seen with two small fluid levels, generally one in each limb of the loop. While the bowel is active it strives to press its contents past the obstruction and it is for this reason that the column of gas shows upright loops that are arched in form on account of peristaltic movement. On fluoroscopic examination the fluid levels rise and fall with fluid levels at different heights in the same loop. It is the rule that the nearer strangulation is approached the less the peristalsis is seen. Repeat examinations may be necessary to demonstrate the peristaltic movement. There is some distention of the prestenotic loops with persistence of the circular folds of the mucosa. The portion of the intestines below the stenosis will contract and tend to empty its contents. It is important to notice that there is an absence of fluid levels if there is a small amount of gas retained in the colon. The contents of the colon below the stenosis should be solid. In some cases there is rapid exudation of fluid into the peritoneal cavity. If the ileus persists a few days the gas usually increases in amount and the number of loops increase; these loops then lie above one another and extend as bands across the abdomen to produce a stepladder effect. There is seldom gas in the stomach.

In strangulation ileus there are many degrees of incarceration. In cases of this type when the compression is slight the findings are those of a simple obstruction. Some of the cases show scant findings. If the strangulation is incomplete there is gas both above the stenosis and in the involved loop. The fluid levels tend to remain more at equal heights than in simple obstruction. In some cases in which the incarceration and stenosis are complete there is a typical picture of ileus, while in others there are scanty signs. The incarcerated loops may produce a tumorlike opacity with a multicircular border. A mechanical ileus of the colon sometimes produces a picture that will resemble that of an ileus of the small bowel especially if the obstruction is in the cecum near the ileocecal valve. In cases of this type the ileocecal valve is usually open which allows the adjacent small bowel to distend. In obstruction of the colon there is fluid and air above the stenosis with

formation of fluid levels in the horizontal ray. The colon below the obstruction is empty. A barium enema will decide the diagnosis.

Paralytic ileus is distinguished from mechanical ileus principally in that both the small and large intestines are affected. Because of diminished peristalsis the bowels are not definitely hoop-shaped but long and lax. Gas and fluid are retained in both portions of the gut and are uniformly spread according to the severity of the paralysis. In the colon the fluid levels are fragmented. In peritonitis there is fluid between the intestines and obliteration of the extraperitoneal layer of fat.

In mesenteric thrombosis the differential diagnosis is between an ileus of the small intestine and a peritoneal reaction. The roentgen findings in this condition are difficult to define correctly and the diagnosis of peritoneal irritation only may be made. Gas filled loops of the small intestine with fluid levels and fluid and gas in the ascending colon may be found in some cases.

A long-standing mechanical ileus and a paralytic ileus are difficult to differentiate. An acute abdominal condition is best investigated without barium, however a small amount of barium may be given by mouth to aid in the determination of the site of the obstruction. The fluid in the loops of bowel above the stenosis dilute the barium. Repeated examinations may provide evidence of whether the condition is deteriorating or improving and are likewise an especially good basis for determining the indications for operation.

FRANK L. HUSSEY, M.D.

Microarteriography. A. E. BARCLAY. *Brit J Radiol* 1947, 20, 394.

During the course of experimental study of the intrarenal vascular system in rabbits to determine the causation of traumatic necrosis, it was soon suspected that under certain conditions the blood circulating through the kidney takes a short cut from the arterial to the venous side leaving the cortex either partially or completely ischemic. It became desirable, therefore to work out a much finer radiographic technique than that customarily used to demonstrate these arteriovenous communications.

The author describes the various stages of development of such a procedure until finally a satisfactory technique has been obtained.

Photographic emulsions. Owing to the rather large size of grains, the ordinary radiographic films were found unsuitable. The author experimented with four types of photographic emulsions: (1) the Ilfex a radiographic film which is employed with out intensifying screens and was used chiefly for radiography of the excised specimens; (2) the Process, an emulsion employed for lantern slides and contact film reproduction; (3) the Kodak film which was much favored during the war for miniature photography; and (4) the Maximum Resolution or more recently the Kodak 500 type MR plates emulsion No. 1565 both of which are capable of resolutions to 1,000 lines.

Fig. 1

Fig. 1 (Barclay) Contact print of a roentgenograph of a section (240u) of a rabbit kidney injected with radiopaque material. Factors: Crystallography diffraction tube with beryllium window k 15, ma. 50 distance 8 in. maximum resolution plate (Kodak 5 type MR plate, emulsion No. 1565) exposure 3 minutes.

In general the finer the grain the longer the exposure that is necessary. If the factor of Ilfex is taken as 1, Process will need 50 Kodakline 100 and Maximum Resolution 2,000 times the exposure. In other words an exposure of 1 second on Ilfex will be equivalent to an exposure of 30 minutes on Maximum Resolution, all settings remaining the same.

Use of softer rays Since the wall of an ordinary x-ray tube absorbs too much of the very soft radiation diffraction tubes with aluminum beryllium or lithium windows were found more satisfactory. The author first tried a gas filled diffraction tube and with a Maximum Resolution film he obtained such fine detail that the kidney vessels were visualized down to those of capillary size.

The present apparatus consists of a half wave transformer coupled up to a Blachlett shockproof hot cathode diffraction tube, operating at 5 to 50 kv. and up to 50 ma. To eliminate the vibration which is a disturbing factor a special casing was made which encloses the tube head and thereby renders the unit not only self-contained but also safe from stray radiation. Hence the room which houses the apparatus can also be used as the dark room.

Technique The radiographic factors depend on the thickness of the specimen. The organ is injected with radio-opaque material, in vivo or after excision and is fixed in the usual way. After the whole organ is radiographed sections are made of areas that give the maximum vascular pattern for study. The most suitable thickness of the sections is from 120 u. to 450 u.

Mounting of specimen It is desirable that the specimen be in direct contact with the emulsion. The floating of the section into position in water or a 50 per cent mixture of water and glycerine is unsatisfactory since wet films lose their sensitivity to a considerable extent. After numerous investigations the author found that the tissue supplied for heat mounting of prints constitutes the most satisfactory waterproof material. Therefore the section (after being washed in water and placed in 50 per cent glycerine and water to prevent evaporation when long exposure is necessary) is transferred on the tissue, the surplus fluid is blotted out, and the tissue is placed on the film in the cassette which is then exposed. At a distance of 8 inches and with a current of 50 ma. the exposure of a section of 240 u. on

Fig. 2 (Barclay) Enlargement (15x) from roentgenograph Fig. 1

Maximum Resolution film amounts to 5 minutes when using 50 kv. and 1 1/4 minutes when using 20 kv.

Injection media. Opaque media used for angiography fall into 3 categories (1) true solutions including diodrast, uroselectan, pyelosal, etc., all of which contain iodine (2) colloidal preparations, including thorocontrast, colloidal metallic gold (red), 15 per cent colloidal silver iodide and colloidal metallic bismuth and (3) insoluble metallic salts, including bismuth carbonate, red lead and jeweller's rouge. The author found that thorocontrast, colloidal gold, silver and bismuth pass readily through the capillaries to the venous side. The jeweller's rouge may also prove to be of value.

Enlargements The contact radiograph represents a true size of the organ or section examined showing the injected radio-opaque material distributed in the vessels. (Fig. 1) This negative can be enlarged by means of a good lens on ordinary photographic paper to about 10 to 15 times, giving the vascular pattern as a whole and thus forming a link between the macroscopic and the microscopic methods of study (Fig. 2) By making a photomicrograph of the negative a further magnification is obtained, up to 50 times. This permits a visualization of the detail of the capillaries and every injected vessel (Fig. 3) Finally by enlarging the photomicrograph on ordinary photographic paper it is possible to obtain

Fig. 3 (Barclay) Photomicrograph (x 50) of roentgenogram. Taken from cortex of kidney, Fig. 1 showing the glomeruli, afferent and efferent vessels, and the subcapsular network of capillaries.

another 5 fold magnification giving a total enlargement of 250 (Fig. 4) T. LELCOTIA M.D.

Giant Cell Tumors of Bone. FRANKLIN B. BOGART and ALLISON E. IMLER *Radiology* 1947 49 432

From January 1, 1942 to October 1, 1945 a total of 656 patients were admitted to an army hospital designated as Radiation Therapy Center. Of these, 10 had giant cell tumors of bone. The authors present 4 cases which are illustrative of various features of the disease. In 3 the giant cell tumor was located in the spine and in the fourth case the tumor was at the upper end of the tibia.

While most giant cell tumors of bone are benign a few become malignant or are malignant from the onset. To establish a correct diagnosis routine biopsy is desirable. With present-day surgical skill no hazard is involved in such a procedure.

If the tumor is proved to be malignant radical surgery is indicated in cases in which the lesion is accessible. Patients in whom the tumor appears to be benign may be treated by radiation therapy. The use of relatively small doses is advocated. The authors agree with the assertion of Pfahler and Parry that when there is no damage to skin and soft tissues there will be none to the epiphyses. In children, a series of approximately 100 to 200 roentgens delivered into the tumor and repeated at intervals of from 1 to 3 months for two to four series appears entirely safe. In adults the authors used a

Fig. 4. (Barclay) Enlargement (x 250) of a group of glomeruli from photomicrograph, Fig. 3, i.e. an enlargement from Fig. 1 of x 250

tumor dose as high as 1,500 roentgens with a second series of half that amount 2 months later but this does not seem to be necessary.

A combination of surgery and radiation therapy, as is often advised for the treatment of giant cell tumors, is not always recommendable. In structures such as the spine for example it is disadvantageous

to use even curettage. As a rule, tumors which have been treated surgically from the beginning and which recur should again be treated surgically as their subsequent response to radiation is unsatisfactory.

The authors are of the opinion that if a malignant change has been discovered later it is probable that the tumor was malignant to start with. It is illogical to assume that the malignant transformation was induced by the irradiation or some other causative agent. A bibliography of 28 articles is appended.

The Clinical Sequence of Physiological Effects of Ionizing Radiation in Animals. C. LADD PROSSER, E. E. PAINTER, HERMAN LISCO, AUSTIN M. BRUCE, and Others. *Radiology* 94:7 40 299.

This report is on work done in the Metallurgical Laboratory of Chicago under the Manhattan Project. The authors believe there is need for a better understanding of the clinical effects produced by exposure to various types of both internal and external radiation. They worked with chickens, rabbits, mice, rats and dogs, using radiations from the x-ray tube, cyclotron, and uranium pile, as well as those of internally administered radioactive isotopes.

Various doses given at different exposure rates gave varying results in the different species, but the authors were able to present four main generalizations on the basis of their detailed study of the animal physiology before death and the microscopic pathological histology after death. These were as follows:

1. Every kind of ionizing radiation is similar in its clinical action whether it be penetrating external radiation or internal radiation from deposited material.

2. Nearly every organ system is affected by lethal doses of every type of radiation. Some of the effects are direct and others are indirect.

3. No single clinical reaction is peculiarly specific for radiation damage.

4. The clinical picture and the conditions resulting in death vary with the dose rate and the duration

of exposure for both external and internal radials. If an animal survives one depression with a onset of symptoms, he is apt to die later of a direct mechanism.

The authors have identified a series of data patterns which lead to death after irradiation.

1. Immediate death due to the administration of a high dose and dose rates causing rapid cellular destruction.

2. Initial shocklike death in about 48 hours, due chiefly in rabbits and chickens. The symptoms were prostration, vomiting, diarrhea, and anorexia, and a fall in blood pressure, granulocytosis, and hypopenia.

3. Early death in from 4 to 6 days with evidence of dehydration, hemoconcentration, intestinal emaciation, and leucopenia.

4. Acute deaths, comprising most of the deaths from all types of ionizing radiation except external beta rays. They occur in from 9 to 21 days after treatment. There is severe leucopenia, thrombocytopenia, bleeding, altered water balance, terminal tetanic fever, reversal of the albumin globulin ratio, high nonprotein nitrogen, high serum protein, and cardiovascular failure.

5. Subacute changes leading to death later. There was aplastic anemia, hyperplastic macrocytic anemia, liver degeneration, emaciation, and bone and bone marrow lesions.

6. Chronic irradiation deaths which occurred from 3 to 24 months or more after treatment. In this group tumors are the important cause. Ovarian tumors have resulted from gamma and x-irradiation. Leucemias have been accelerated in appearance by penetrating irradiation. Skin carcinoma has resulted from external beta radiation. Bone sarcomas appear after prolonged irradiation with strontium 90 and Pu and Ra. Premature aging, emaciation, and other types of chronic irradiation injury lead to death after prolonged exposure at low dose rates.

The whole article is very timely with the increasing availability of many radioactive isotopes and should stimulate all to inquire deeply into the many hazards of this type of radiation.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

The Thermostability of the Toxin Components of Clostridium Welchii Type A J. H. MASOX
S Afr J Med Sc 1947 13 61

The alpha toxin of the *Clostridium welchii* is heat stable to a considerable extent. It is not completely destroyed when heated to 120 C. for an hour. The theta toxin is heat labile.

Autoclaved toxin stimulates the formation of alpha antitoxin when it is injected into rabbits and horses.

A small quantity of Welch alpha antigen is retained in pulp used for clarifying *Clostridium welchii* cultures even when the pulp is subsequently autoclaved and washed. When such pulp is used to clarify a *Clostridium septicum* culture sufficient Welch antigen is carried over into the septicum toxin to stimulate the formation of Welch alpha antitoxin in horses in which this septicum toxin is used for hyperimmunization purposes.

Experiences in the Surgical Treatment of Multiple Visceral Neoplasms. ALEXANDER BRONSCHEIN and PAUL W. SCHAEFER. *Ann Surg* 1947 126 780

The case histories of 9 patients in whom there was a multiplicity of malignant or benign symptom-producing neoplasms of various viscera are reviewed. They are classified into three groups:

1. Those with multiple tumors situated close to one another and producing symptoms clinically attributable to one growth. In these patients the multiplicity of the growths was discovered only at operation or upon study of the pathologic specimens.

2. Those with 2 tumors rather widely separated and manifesting simultaneously the symptomatology of 2 separate growths.

3. Those in whom one growth was excised to be followed later by the development of a second independent growth which in turn was also resected.

In this series the stomach was the site of multiple neoplasms in 2 instances, the colon in 3 instances, the larynx and the esophagus in 1 instance, the esophagus and the stomach in 1 instance, the stomach and the colon in 1 instance, and the papilla of Vater and the colon in 1 instance. Not all of the lesions were malignant. In 2 instances the lesion in the stomach was benign and in 1 instance one of the colonic lesions was benign, but in 2 of these cases the benign lesions produced symptoms.

The classical teaching is to ascribe as often as possible all symptomatology to one pathologic process. In the case of neoplasms, especially malignant, recurrence of symptomatology in the great majority of instances is due to recurrence of the neoplasm and/or its metastases. However, sufficient data has

now been published to indicate that the multiplicity of neoplasms producing symptoms synchronously or successively as they develop is not an extreme rarity and in the follow up of patients having had one neoplasm resected this possibility is to be borne in mind.

Protein-Chemical Aspects of Cancer GERALT TORX
Adv. Cancer Res., 1947 7 193

This is a summation of the important data obtained to date regarding the protein-chemical aspects of cancer. Because of poorly developed micro-technique and because of the structural organization of the cell an overall analysis obviously affords limited insight into the significance of changes in chemical composition. The recent development of analysis by means of isotope dilution and micro-biological assay have greatly increased the analytical precision and specificity for many proteins. More useful information awaits future developments.

Radical Treatment of Malignant Melanomas of the Lower Extremities. ERNEST M. DALAND
Surg Clin N America 1947 27 1136

This article reports the history and course of 3 cases of malignant melanomas of the lower extremity which spread along the subcutaneous lymphatics and involved the saphenous and inguinal nodes. Radical surgical treatment consisted in the removal of the primary lesion, regional node dissection and excision of all the intervening skin, fat and fascia.

The patients are free from disease 13½, 3½ and 3 years later respectively although in each case several operative procedures for removal were required before the lesions were completely eradicated. There has been no permanent disability from the operative treatment. STEPHEN A. ZIEGLER, M.D.

Report of Clinical Experiences with Homografts. W. P. LONGBRIDGE, JR., H. B. STONE, A. S. DANIEL, and C. D. GOODE. *Plast Reconstr Surg* 1947 2 419

As the popularity of free skin grafting spread in the latter part of the nineteenth century it was generally accepted that skin from one person could be grafted on another and the literature contained numerous reports of successful homografts.

From 1910 on published reports indicate that homografting in human beings has not been permanently successful. Investigations have indicated that blood groupings of donor and recipient have nothing to do with the permanent take of a homograft. The only clearly authentic cases of permanently successful homografts were presented by Brown and McDowell in monozygotic twins.

Medawar approaches the problem of making a successful homograft by trying (a) to alter the tissues of the graft so they are no longer antigenic to

to use even curettage. As a rule, tumors which have been treated surgically from the beginning and which recur should again be treated surgically as their subsequent response to radiation is unsatisfactory.

The authors are of the opinion that if a malignant change has been discovered later it is probable that the tumor was malignant to start with. It is illogical to assume that the malignant transformation was induced by the irradiation or some other causative agent. A bibliography of 28 articles is appended.

STEPHEN A ZIMMAN, M D

Report of Clinical Experiences with Homografts. W P LONGMIRE JR, H B STONE, A S DANIEL, and C D GOOM. *Plast Reconstr Surg*, 1947 2 419

As the popularity of free skin grafting spread in the latter part of the nineteenth century, it was generally accepted that skin from one person could be grafted on another, and the literature contained numerous reports of successful homografts.

From 1910 on published reports indicate that homografting in human beings has not been permanently successful. Investigations have indicated that blood groupings of donor and recipient have nothing to do with the permanent take of a homograft. The only clearly authentic cases of permanently successful homografts were presented by Brown and McDowell in monozygotic twins.

Medawar approaches the problem of making a successful homograft by trying (a) to alter the tissues of the graft so they are no longer antigenic to

the host (b) to find a donor whose unaltered tissues are compatible with those of the recipient.

In the authors' experiments pinch grafts were transferred simultaneously from 71 donors to a single recipient. Although all grafts "took" none were permanent. Thirty-two grafts showed spreading epithellum for 24 days, then rapidly disappeared thereafter. At the time of final observation (the fifty-fourth day) two collagenous pads were all that remained of the grafts.

The results indicate mathematically that if skin transplantation groups do exist there are at least 23 in number.

Histological studies of a homograft transplanted as a pinch graft into a bed surrounded by normal skin suggest that what appears to be a permanent survival of the homograft is actually an overgrowth of the area by the tissue of the host.
